Received May 3, 2009, in final form May 27, 2009

The coordinate Bethe ansatz solutions of the  $XXZ$  model for a one-dimensional spin-1/2 chain are analyzed with focus on the statistical properties of the constituent quasiparticles. Emphasis is given to the special cases known as  $XX$ ,  $XXX$ , and Ising models, where considerable simplifications occur. The  $XXZ$  spectrum can be generated from separate pseudovacua as configurations of sets of quasiparticles with different exclusion statistics. These sets are complementary in the sense that the pseudovacuum of one set contains the maximum number of particles from the other set. The Bethe ansatz string solutions of the  $XXX$  model evolve differently in the planar and axial regimes. In the Ising limit they become ferromagnetic domains with integer-valued exclusion statistics. In the  $XX$  limit they break apart into hard-core bosons with (effectively) fermionic statistics. Two sets of quasiparticles with spin 1/2 and fractional statistics are distinguished, where one set (spinons) generates the  $XXZ$  spectrum from the unique, critical ground state realized in the planar regime, and the other set (solitons) generates the same spectrum from the twofold, antiferromagnetically ordered ground state realized in the axial regime. In the Ising limit, the solitons become antiferromagnetic domain walls.

**Key words:**  $XXZ$  model, Bethe ansatz, string hypothesis, fractional statistics, spinons, solitons

### 1. Introduction

Quantum spin chains are physically realized in quasi-one-dimensional magnetic compounds. These are crystalline materials with magnetic ions arranged in exchange-coupled chains that are isolated from each other by non-magnetic ions. The elementary magnetic moments are localized on the sites  $l$  of a one-dimensional lattice, which makes them distinguishable. Thus, the associated spin operators commute if they belong to different sites of that lattice,  $[S_l^\alpha, S_{l'}^\beta] = i\hbar\epsilon_{\alpha\beta\gamma}S_l^\gamma\delta_{ll'}$ . The Hilbert space of a spin-1/2 chain with  $N$  sites is conveniently spanned by product basis vectors  $|\sigma_1 \dots \sigma_N\rangle$ ,  $\sigma_l = \uparrow, \downarrow$ .

Prominent among the many models employed in the context of quantum spin chain compounds is the spin-1/2  $XXZ$  model,

$$\mathcal{H}_{XXZ} = J \sum_{l=1}^N \{S_l^x S_{l+1}^x + S_l^y S_{l+1}^y + \Delta S_l^z S_{l+1}^z\}. \quad (1)$$

It describes a uniform nearest-neighbor exchange coupling with uniaxial anisotropy. Periodic boundary conditions are assumed. We distinguish ferromagnetic coupling ( $J < 0$ ) from antiferromagnetic coupling ( $J > 0$ ), and the planar regime ( $0 \leq \Delta < 1$ ) from the axial regime ( $\Delta > 1$ ). Important special cases are the  $XX$  model ( $\Delta = 0$ ), the  $XXX$  model ( $\Delta = 1$ ), and the Ising model ( $\Delta \rightarrow \infty$ ).

One persistent challenge through decades of experiments on quantum spin chain compounds has been the interpretation of the observed intensity spectrum in terms of constituent quasiparticles [1,2]. The chief motivation of the work reported here is to shed new light on this very issue. The approach taken is eclectic in nature, combining older and more recent results for the unified purpose of understanding the quasiparticle composition of the  $XXZ$  spectrum more thoroughly.

The strong interest in the  $XXZ$  model is sustained not only by its direct relevance in experimental physics, but also by its amenability to exact analysis via Bethe ansatz. The solution of

the  $XXX$  model was, in fact, the very problem for which Bethe originally invented the method in the early days of quantum mechanics [3,4]. The Bethe ansatz allows for a characterization of all many-body eigenstates as composed of quasiparticles that scatter off each other or form bound states and thus turn into different quasiparticles. Over the years the same basic idea has been successfully applied to many different kinds of systems and situations including interacting boson and fermion gases with contact interactions [5–7], the Hubbard model for electrons on a lattice with on-site repulsion [8,9], and for bosonic and fermionic quantum field theories including the quantum Sine-Gordon and Thirring models [10].

The  $XXZ$  spectrum can be generated from different pseudovacua by the systematic creation of quasiparticles with different exclusion statistics. In most cases these pseudovacua are states of lowest energy (physical vacua). An overview of the different kinds of quasiparticles that have emerged from analytic work on the  $XXZ$  model is shown in figure 1. The boxes in the top row represent quasiparticles whose names are derived from jargon used to describe coordinate Bethe ansatz solutions. These quasiparticles are characterized by strings of complex momenta with common real part and different imaginary parts [7]. One-strings are unbound magnons, two-strings are bound magnon pairs etc. Small (large) imaginary parts indicate loose (tight) binding [11]. At  $\Delta = 1$  the strings are constituent particles of (degenerate) multiplets of eigenstates with total spin  $S_T$ . These multiplets split up energetically at  $\Delta \neq 1$ .

**Figure 1.** Zoo of quasiparticles that play some role in the context of the  $XXZ$  model. For  $J > 0$ , the pseudovacua of spinons and solitons are at the bottom of the spectrum. The pseudovacuum of the string particles is at the top in the axial regime ( $\Delta \geq 1$ ) and moves downward in the planar regime ( $0 \leq \Delta \leq 1$ ), reaching the center in the  $XX$  limit and coinciding there with the pseudovacuum of Jordan-Wigner fermions.

At  $\Delta = 0$  the energy levels join up in new degenerate configurations, reflecting different symmetries [12–17]. A more natural classification scheme for the  $XX$  spectrum is then based on string fragments. Hence the name *broken strings*. These fragments are closely related to the free lattice fermions that emerge from the Jordan-Wigner representation of spin-1/2 operators [12,15–17]. At  $\Delta > 1$  the imaginary parts of the string solutions grow in magnitude and diverge as  $\Delta \rightarrow \infty$ . Hence the name *stretched strings*. The tightly bound strings are related, in the Ising limit, to localized domains of reversed spins on successive lattice sites. The exclusion statistics of these domains is similar to yet subtly different from that of the strings.

The boxes in the bottom row of figure 1 represent quasiparticles that are complementary to the string particles. The string pseudovacuum contains the maximum number of spinons or solitons. The spinon and soliton vacua contain strings at maximum capacity. Whereas the string particles have integer-valued exclusion statistics, the spinons and solitons are realizations of fractional statistics [18]. They are both semions but with different pseudovacua. The exclusion principle for semions is, roughly speaking, halfway between those applicable for fermions and bosons. If it takes  $1/g$  particles to lower the number of orbitals in a band available for occupancy by one, then  $g = 1$  describes fermions,  $g = 1/2$  semions, and  $g = 0$  bosons (as a limit).

The string particles and the semionic particles are natural building blocks for the systematic construction of a complete  $XXZ$  eigenbasis from different pseudovacua. The configurations of

string particles and semionic particles are both unique and preserved in every  $XXZ$  eigenstate. The ground state (physical vacuum) of the  $XXZ$  antiferromagnet ( $J > 0$ ) coincides with the pseudovacua of the semions. The spinon vacuum is unique and coincides with the non-degenerate ground state of the  $XXZ$  model at  $0 \leq \Delta \leq 1$  for even  $N$ . The soliton vacuum is twofold and coincides with the ground state of the  $XXZ$  model at  $\Delta > 1$  for  $N \rightarrow \infty$ .

Let us briefly illustrate the relation between the particles from the top and bottom rows in figure 1 with two simple scenarios, one in configuration space and the other in momentum space. In the Ising limit,  $\mathcal{H}_{XXZ}$  has simple product eigenstates. The ferromagnetic state  $|\uparrow\uparrow\uparrow \dots\rangle$  is the unique pseudovacuum for domains of consecutive flipped spins,  $\downarrow\downarrow \dots \downarrow$ , as shown in top part of figure 2. The twofold Néel state,  $|\uparrow\downarrow\uparrow \dots\rangle$ ,  $|\downarrow\uparrow\downarrow \dots\rangle$ , by contrast, is the pseudovacuum for antiferromagnetic domain walls of the kind  $\uparrow\uparrow$ ,  $\downarrow\downarrow$  as shown in the bottom part of figure 2. These domain walls (named solitons) have effective spin  $\pm 1/2$ . The integer-valued exclusion statistics of domains is associated with the fact that neighboring particles must be separated by any positive integer number of lattice sites. The fractional exclusion statistics of domain walls, on the other hand, are associated with the fact that one of two lattice sites may be shared by neighboring particles.

**Figure 2.** Constituent quasiparticles of  $\mathcal{H}_{XXZ}$  at  $\Delta \rightarrow \infty$  in real space (lattice of  $N$  sites). They are either domains of flipped spins embedded in the unique vacuum with all spins up (top) or domain walls embedded in the twofold vacuum with all spins alternatingly up/down (bottom).

**Figure 3.** Constituent quasiparticles of  $\mathcal{H}_{XXZ}$  at  $\Delta = 0$  in reciprocal space (fermionic band with Fermi momentum  $k_F$ ). They are either spinless Jordan-Wigner fermion or semionic spinons with spin  $\pm 1/2$ .

In the  $XX$  limit,  $\mathcal{H}_{XXZ}$  is equivalent to a system of  $N_F$  free lattice fermions in a band [19–22]. The ground state corresponds to the intact Fermi sea at  $|k| < k_F$  as shown in figure 3. The entire spectrum can be generated systematically via particle excitations ( $\Delta N_F = +1$ ), hole excitations ( $\Delta N_F = -1$ ), and particle-hole excitations ( $\Delta N_F = 0$ ). The Fermi-sea ground state can be viewed

as the pseudovacuum for semionic spinons. We introduce a threshold momentum  $k_c$  that varies with  $N_F$ . When a fermion is removed from the intact sea,  $k_c$  slightly increases to generate not just one but two vacancies in the interval  $|k| < k_c$  of the band. These two holes are then identified with a pair of spin-up spinons. When a fermion is added outside the intact Fermi sea,  $k_c$  slightly decreases to produce two particles in the region  $|k| > k_c$ . They are identified with a pair of spin-down spinons. A fermionic particle-hole excitation leaves  $k_c$  unchanged and is interpreted as a pair of spinons with opposite spin orientation. Thus, the entire spectrum can be described in the form of spinon configurations.

The main goal of this work is to identify the relationship between the string particles and the semionic particles for  $\mathcal{H}_{XXZ}$  at  $\Delta = 0, 1, \infty$  in particular and to illuminate how this relationship can be tracked between the three points in parameter space. In section 2 we set the stage for this investigation by reviewing the relevant Bethe-ansatz representations that best serve our purpose. Then we discuss the quasiparticle composition of the  $XXZ$  spectrum in the  $XXX$  limit (section 3.1), the Ising limit (section 3.2), and the  $XX$  limit (section 3.3).

## 2. Bethe ansatz

The coordinate Bethe ansatz for  $\mathcal{H}_{XXZ}$  uses the magnon vacuum  $|F\rangle \equiv |\uparrow\uparrow \cdots \uparrow\rangle$  with energy  $E_F = JN\Delta/4$  as its reference state. The Bethe form [3] of any eigenvector in the invariant subspace with magnetization  $M_z = N/2 - r$ ,

$$|\psi\rangle = \sum_{1 \leq n_1 < \dots < n_r \leq N} a(n_1, \dots, n_r) S_{n_1}^- \cdots S_{n_r}^- |F\rangle, \quad (2)$$

has coefficients of the form

$$a(n_1, \dots, n_r) = \sum_{\mathcal{P} \in S_r} \exp \left( i \sum_{j=1}^r k_{\mathcal{P}j} n_j + \frac{i}{2} \sum_{i < j}^r \theta_{\mathcal{P}i\mathcal{P}j} \right), \quad (3)$$

determined by  $r$  magnon momenta  $k_i$  and one phase angle,  $\theta_{ij} = -\theta_{ji}$ , for each magnon pair. The sum  $\mathcal{P} \in S_r$  is over the permutations of the indices  $\{1, 2, \dots, r\}$ . The  $k_i$  and  $\theta_{ij}$  satisfy the Bethe ansatz equations (BAE),

$$e^{iNk_i} = \prod_{j \neq i}^r e^{i\theta_{ij}}, \quad e^{i\theta_{ij}} = - \frac{e^{i(k_i+k_j)} + 1 - 2\Delta e^{ik_i}}{e^{i(k_i+k_j)} + 1 - 2\Delta e^{ik_j}}. \quad (4)$$

The energy and the wave number of an eigenstate with magnon momenta  $\{k_1, \dots, k_r\}$  are

$$\frac{E - E_F}{J} = \sum_{i=1}^r (\cos k_i - \Delta), \quad k = \left( \sum_{i=1}^r k_i \right) \text{mod}(2\pi). \quad (5)$$

Reasons of practicality dictate the use of different transformations of the BAE in the regimes of axial anisotropy ( $\Delta > 1$ ), planar anisotropy ( $\Delta < 1$ ), and isotropic exchange ( $\Delta = 1$ ). It is convenient to introduce rapidities  $z_i$ ,

$$\cot \frac{k_i}{2} = \begin{cases} \cot \frac{\gamma}{2} \tanh \frac{\gamma z_i}{2} & : 0 \leq \Delta = \cos \gamma < 1, \\ z_i & : \Delta = 1, \\ \coth \frac{\eta}{2} \tan \frac{\eta z_i}{2} & : \Delta = \cosh \eta > 1, \end{cases} \quad (6)$$

which renders the limit  $\Delta \rightarrow 1$  smooth from both sides. Thus, the BAE (4) transform into

$$N\tilde{\phi}_1(z_i) = 2\pi I_i + \sum_{j \neq i}^r \tilde{\phi}_2(z_i - z_j), \quad i = 1, \dots, r, \quad (7)$$

where

$$\tilde{\phi}_\nu(z) \doteq \begin{cases} 2 \arctan \left( \cot \frac{\gamma\nu}{2} \tanh \frac{\gamma z}{2} \right) & : 0 \leq \Delta < 1, \\ 2 \arctan \frac{z}{\nu} & : \Delta = 1, \\ 2 \arctan \left( \coth \frac{\eta\nu}{2} \tan \frac{\eta z}{2} \right) & : \Delta > 1. \end{cases} \quad (8)$$

The Bethe quantum numbers (BQN)  $I_i$  of integer or half-integer value reflect the multivaluedness of the logarithm used in the transformation. They are subject to restrictions that will be discussed case by case. The energy expression in (5) becomes

$$\frac{E - E_F}{J} = - \sum_{i=1}^r \tilde{e}(z_i), \quad \tilde{e}(z) \doteq \begin{cases} \frac{\sin^2 \gamma}{\cosh(\gamma z) - \cos \gamma} & : 0 \leq \Delta < 1, \\ \frac{2}{1 + z^2} & : \Delta = 1, \\ \frac{-\sinh^2 \eta}{\cos(\eta z) - \cosh \eta} & : \Delta > 1. \end{cases} \quad (9)$$

Note that we are, effectively, dealing with a single anisotropy parameter,  $\eta = \nu\gamma$ , that is real in one regime, imaginary in the other, and zero at the isotropy point. This parametrization is particularly useful for tracking the spectrum between the axial and planar regimes across the point of higher rotational symmetry. Slightly different parametrizations are more adequate for the exploration of the limits  $\Delta \rightarrow \infty$  in the axial regime and  $\Delta \rightarrow 0$  in the planar regime.

## 2.1. Axial regime

At  $\Delta > 1$  we use the transformation [23],

$$\tan \frac{z_i}{2} \doteq \tanh \frac{\eta}{2} \cot \frac{k_i}{2}, \quad \eta = \operatorname{arcosh} \Delta, \quad -\pi < z_i < \pi, \quad (10)$$

instead of (6), to bring the BAE (4) into the form

$$\left( \frac{\coth(\eta/2) \tan(z_i/2) - \iota}{\coth(\eta/2) \tan(z_i/2) + \iota} \right)^N = \prod_{j \neq i}^r \frac{\coth(\eta) \tan[(z_i - z_j)/2] - \iota}{\coth(\eta) \tan[(z_i - z_j)/2] + \iota}, \quad i = 1, \dots, r. \quad (11)$$

The associated trigonometric BAE are

$$N \phi_1(z_i) = 2\pi I_i + \sum_{j \neq i}^r \phi_2(z_i - z_j), \quad i = 1, \dots, r, \quad (12)$$

where

$$\phi_\nu(z) \doteq 2 \arctan \left( \frac{\tan(z/2)}{\tanh(\eta\nu/2)} \right) + 2\pi \left\lfloor \frac{\Re z}{2\pi} + \frac{1}{2} \right\rfloor. \quad (13)$$

The second term in (13) ensures that the set  $\{I_i\}$  remains the same as an eigenstate is tracked across the axial regime [7]. Here  $\lfloor x \rfloor$  is the floor function (integer part of  $x$ ).

For the analysis of solutions that include complex magnon momenta we invoke the string hypothesis for the rapidities [7]:

$$z_\alpha^{m,l} = z_\alpha^m + \imath\eta(m + 1 - 2l), \quad l = 1, \dots, m, \quad m = 1, 2, \dots, r. \quad (14)$$

The index  $l$  distinguishes rapidities belonging to the same string (of size  $m$ ). The index  $\alpha = 1, \dots, n_m$  distinguishes different strings of the same size. The string ansatz (14) produces only asymptotic solutions of the BAE (11) for  $N \rightarrow \infty$ . The finite- $N$  corrections are, in general, exponentially small, and not all finite- $N$  solutions fit the string template (14) [7]. However, neither

corrections nor exceptions affect macroscopic systems. In the Ising limit, where the spread of imaginary parts in (14) diverges, all corrections and exceptions disappear even for finite  $N$ .

A given string solution of (11) with magnetization  $M_z = N/2 - r$  is described by  $r$  rapidities that breaks down into configurations of strings such that the constraint,

$$\sum_{m \in \mathcal{C}} m n_m = r, \quad (15)$$

is satisfied, where the set  $\mathcal{C}$  identifies those sizes of strings that occur in a given eigenstate. With the functions

$$\varphi_\nu(z) \doteq \frac{\coth(\eta\nu/2) \tan(z/2) - \imath}{\coth(\eta\nu/2) \tan(z/2) + \imath} = \frac{\sin\left(\frac{z - \eta\nu}{2}\right)}{\sin\left(\frac{z + \eta\nu}{2}\right)} \quad (16)$$

we rewrite equations (11) in the form

$$[\varphi_1(z_i)]^N = \prod_{j \neq i}^r \varphi_2(z_i - z_j), \quad i = 1, \dots, r. \quad (17)$$

When we substitute the string ansatz (14) into equations (17) we obtain

$$[\varphi_1(z_\alpha^{m,l})]^N = \prod_{(m',\beta) \neq (m,\alpha)} \prod_{k=1}^{m'} \varphi_2(z_\alpha^{m,l} - z_\beta^{m',k}) \prod_{k \neq l}^m \varphi_2(z_\alpha^{m,l} - z_\alpha^{m,k}), \quad (18)$$

for  $l = 1, \dots, m$  and  $\alpha = 1, \dots, n_m$ , where

$$\varphi_\nu(z_\alpha^{m,l}) = \frac{\sin\left(\frac{[z_\alpha^m + \eta(m+1-\nu-2l)]/2}{2}\right)}{\sin\left(\frac{[z_\alpha^m + \eta(m+1+\nu-2l)]/2}{2}\right)}. \quad (19)$$

To determine the real parts,  $z_\alpha^m$ , we form the product of all equations (18) for fixed  $m, \alpha$ :

$$\left[ \prod_{l=1}^m \varphi_1(z_\alpha^{m,l}) \right]^N = \prod_{(m',\alpha') \neq (m,\alpha)} \left[ \prod_{k=1}^{m'} \prod_{l=1}^m \varphi_2(z_\alpha^{m,l} - z_{\alpha'}^{m',k}) \right] \left[ \prod_{l=1}^m \prod_{k \neq l}^m \varphi_2(z_\alpha^{m,l} - z_\alpha^{m,k}) \right]. \quad (20)$$

Each expression in square brackets can be simplified massively, producing the BAE for the  $z_\alpha^m$ ,

$$[\varphi_n(z_\alpha^m)]^N = \prod_{(m',\alpha') \neq (m,\alpha)} \varphi_{m'-m}(z_{\alpha\alpha'}^{mm'}) \varphi_{m'+m}(z_{\alpha\alpha'}^{mm'}) \prod_{l=1}^{m-1} \left[ \varphi_{m'+m-2l}(z_{\alpha\alpha'}^{mm'}) \right]^2, \quad (21)$$

with  $z_{\alpha\alpha'}^{mm'} \doteq z_\alpha^m - z_{\alpha'}^{m'}$ . The associated trigonometric BAE,

$$N\phi_m(z_\alpha^m) = 2\pi I_\alpha^m + \sum_{(m',\alpha') \neq (m,\alpha)} \Phi_{mm'}(z_{\alpha\alpha'}^{mm'}), \quad (22)$$

$$\Phi_{mm'}(z) \doteq \begin{cases} \phi_{|m-m'|}(z) + 2\phi_{|m-m'|+2}(z) + \dots + 2\phi_{m+m'-2}(z) + \phi_{m+m'}(z) & : m' \neq m, \\ 2\phi_2(z) + 2\phi_4(z) + \dots + 2\phi_{2m-2}(z) + \phi_{2m}(z) & : m' = m, \end{cases} \quad (23)$$

depend on a set  $\{I_\alpha^m\}$  of BQN that reflects the specific string combination of any given eigenstate. The energy and wave number of that state are

$$\frac{E - E_F}{J} = - \sum_{(m,\alpha)} \frac{\sinh \eta \sinh(\eta m)}{\cosh(\eta m) - \cos z_\alpha^m}, \quad k = \left[ \sum_{(m,\alpha)} \left( \pi - \frac{2\pi}{N} I_\alpha^m \right) \right] \text{mod}(2\pi). \quad (24)$$

The range of the  $I_\alpha^m$  will be first discussed for the case  $\Delta = 1$  in section 2.2 and then for the axial regime including the Ising limit in section 3.2.

## 2.2. Isotropic exchange

At  $\Delta = 1$  we retain the rapidities from (6), the trigonometric BAE in the form (7), and the energy expression (9). The string hypothesis now reads

$$z_\alpha^{m,l} = z_\alpha^m + \imath(m+1-2l), \quad l = 1, \dots, m, \quad m = 1, 2, \dots, r. \quad (25)$$

The BAE for the real parts  $z_\alpha^m$  are equations (21) with (19) replaced by

$$\varphi_\nu(z_\alpha^{m,l}) = \frac{z_\alpha^m + \imath(m+1-\nu-2l)}{z_\alpha^m + \imath(m+1+\nu-2l)}. \quad (26)$$

Then, the associated trigonometric BAE for the  $z_\alpha^m$  take on the form (22) with  $\Phi_{mm'}(z)$  from (23) and  $\phi_\nu(z) \doteq 2 \arctan(z/\nu)$  from (8). The energy and wave number of an eigenstate specified by the set  $\{I_\alpha^m\}$  are

$$\frac{E - E_F}{J} = - \sum_{(m,\alpha)} \frac{2m}{m^2 + (z_\alpha^m)^2}, \quad k = \left[ \sum_{(m,\alpha)} \left( \pi - \frac{2\pi}{N} I_\alpha^m \right) \right] \bmod(2\pi). \quad (27)$$

The string hypothesis sets the range of the  $I_\alpha^m$  (with  $I_{\alpha+1}^m > I_\alpha^m$  implied) as follows [7]:

$$|I_\alpha^m| \leq \frac{1}{2} \left( N - 1 - \sum_{m' \in \mathcal{C}} t_{mm'} n_{m'} \right), \quad t_{mm'} \doteq 2\min(m, m') - \delta_{mm'}, \quad (28)$$

where  $n_m$  is the number of  $m$ -strings (distinguished by running index  $\alpha$ ) in the eigenstate. Note that the range of the allowed values becomes narrower for all sizes if a string of any size is added. The  $I_\alpha^m$  for a given combination  $\{n_m\}$  and a given value of  $m$  are either all integers or all half-integers such that the border values of the range (28) are realized.

The Bethe state characterized by a set  $\{I_\alpha^m\}$  is the highest-weight component (i. e. the state with  $M_z = S_T$ ) of an  $S_T$ -multiplet with total spin

$$S_T = \frac{N}{2} - r, \quad r = \sum_{m \in \mathcal{C}} m n_m. \quad (29)$$

The other components of any given  $S_T$ -multiplet are generated by the addition of magnons with zero momentum. These have no effect on the energy or the wave number. Consider the case of a highest-weight state with total spin (29) that only contains 1-strings. Suppose this state is specified by the following set of BQN subject to the constraint (28):

$$-\frac{1}{2}(N-r-1) \leq I_1^1 < \dots < I_r^1 \leq \frac{1}{2}(N-r-1). \quad (30)$$

The rapidities  $z_\alpha^1$  derived from the BAE (22),

$$N\phi_1(z_\alpha^1) = 2\pi I_\alpha^1 + \sum_{\beta \neq \alpha}^r \phi_2(z_\alpha^1 - z_\beta^1), \quad \alpha = 1, \dots, r, \quad (31)$$

are real and, with rare exceptions, finite. The member state with  $M_z = S_T - 1$  of the same multiplet has one extra rapidity,  $z_{r+1} = \infty$ , representing the additional magnon with  $k_{r+1} = 0$ . The BAE (22) for this state are then satisfied with the same  $z_\alpha^1$ ,  $\alpha = 1, \dots, r$  and with  $z_{r+1} = \pm\infty$  if we set the BQN as follows:

$$\tilde{I}_\alpha^1 = I_\alpha^1 \pm \frac{1}{2}, \quad \alpha = 1, \dots, r; \quad \tilde{I}_{r+1}^1 = \pm \frac{1}{2}(N-r). \quad (32)$$

In the more general case, where the highest-weight state under consideration contains strings with  $m > 1$ , the shifts in the already existing BQN,  $I_\alpha^m$ , and the value of the new BQN,  $I_{r+1}^1$ , will be different. In section 3.1 we will treat the strings as interacting particles and examine their exclusion statistics.

### 2.3. Planar regime

The string ansatz at  $\Delta < 1$  [7] will not be used here. Simplifications and residual complications that occur in the limit  $\Delta \rightarrow 0$  can be seen in the raw form (4) of the BAE. There are two categories of solutions, both of which are ubiquitous. Regular and singular solutions are distinguished by the absence or presence of pairs of critical magnon momenta with  $k_i + k_j = \pi$ , which make both the numerator and the denominator in (4) vanish as  $\Delta \rightarrow 0$ .

All regular solutions produce real magnon momenta from  $e^{iNk_i} = (-1)^{r-1}$ , whereas singular solutions include critical magnon pairs that are either both real or form a complex-conjugate pair [12,15–17]. The latter can be interpreted as fragments of strings that exist throughout the planar regime. Since all critical pairs are associated with a twofold degeneracy of eigenstates with equal wave number, the singular features as imposed by the BAE in the limit  $\Delta \rightarrow 0$  can be removed by unitary transformations. This erases, at  $\Delta = 0$ , all traces of the string nature, at  $\Delta > 0$ , of complex solutions. The magnon momenta thus regularized are

$$k_\alpha = \pi - \frac{2\pi}{N} I_\alpha^1. \quad (33)$$

The associated BQN are integers for odd  $r$  and half-integers for even  $r$  with range

$$|I_\alpha^1 - \tau_r| \leq \frac{1}{2}(N - 1), \quad \tau_r = \frac{1}{2}[1 - (-1)^r]. \quad (34)$$

Their relation to the BQN (28) and (32) of the  $S_T$ -multiplet states will be discussed in section 3.3.

The regularized BAE solutions (33) describe hard-core bosons. The phase shift is  $\theta_{ij} = \pi$  for all two-particle interactions. These hard-core bosons are equivalent to the Jordan-Wigner fermions [19–22] that have been instrumental in most studies of the  $XX$  model.

## 3. Quasiparticle composition of $XXZ$ spectrum

We are now ready to explore the relationship between the complementary quasiparticle compositions of the  $XXZ$  spectrum. We begin in section 3.1 with string particles and the complementary spinon particles for the  $XXX$  case. In section 3.2 we discuss the effects of axial anisotropy on the strings and their relationship to ferromagnetic domains in the Ising limit. Complementary to these domains are the soliton particles in the shape of antiferromagnetic domain walls. In the planar regime the strings evolve differently. What remains of them in the  $XX$  limit are fragments that act like hard-core bosons or, equivalently, free Jordan-Wigner fermions. Complementary to the latter are again the spinons as will be discussed in section 3.3.

### 3.1. $XXX$ limit: strings and spinons

The very structure of the coordinate Bethe ansatz suggests that the strings (25) can be interpreted as quasiparticles. There exists a universal energy-momentum relation as implied by (27). The particle interaction is encoded in the set of momenta (or rapidities) dictated by the BAE and in the phase shifts associated with elastic two-particle collisions.

The exclusion statistics of strings is determined by the rule (28) governing the range of BQN and by the relation (29) governing the capacity for strings in a highest-weight state of the given  $S_T$ . The total number of  $S_T$ -multiplets with string content  $\{n_1, n_2, \dots\}$  becomes the solution of a standard combinatorial problem:

$$W(\{n_m\}) = \prod_{m \in \mathcal{C}} \binom{d_m + n_m - 1}{n_m}, \quad d_m = A_m - \sum_{m' \in \mathcal{C}} g_{mm'}(n_{m'} - \delta_{mm'}), \quad (35)$$

where

$$A_m = N + 1 - 2m, \quad g_{mm'} = 2 \min(m, m') \quad (36)$$

are statistical capacity constants and statistical interaction coefficients, respectively, that are specific to the string particles [13,18,24–26]. Taking into account the  $(2S_T + 1)$ -fold degeneracy of each multiplet, this classification accounts for the complete spectrum,

$$\sum_{\{n_m\}} W(\{n_m\})(2S_T + 1) = 2^N, \quad (37)$$

with the dependence of  $S_T$  on  $\{n_m\}$  given in (29).

To illustrate the string composition of the  $XXX$  spectrum and to explain its relationship to the complementary spinon composition we consider a chain of  $N = 6$  sites. In table 1 we list all combinations  $\{n_m\}$  permitted by (29). Also listed is the range of all  $I_\alpha^m$  present in each combination as inferred from (28). Thus, the distinct configurations of  $I_\alpha^m$  allowed produce the highest-weight states of all  $S_T$ -multiplets as shown in figure 4 (left). The quantum number  $S_T$  depends on the combinations  $\{n_m\}$  via (29) and the wave number  $k$  depends on the configurations  $\{I_\alpha^m\}$  via (27). Each row of  $I_\alpha^m$  in figure 4 (left) represents the distinct string motif of an  $S_T$ -multiplet. The solution of the BAE (22) thus specified is for the highest-weight component of the multiplet. The non-highest-weight components are characterized by additional BQN as described at the end of section 2.2. The role of these additional BQN will be discussed in section 3.2 for  $\Delta > 1$  (see figure 5) and in section 3.3 for  $\Delta < 1$  (see figure 6).

**Table 1.** String composition  $\{n_m\}$  of all  $S_T$ -multiplets for  $N = 6$ . Each row describes a distinct combination for a total of 7. Each combination produces  $W$  multiplets for a total of 20. Each multiplet represents  $2S_T + 1$  states for a total of 64. Associated with each string in a given combination is a BQN  $I_\alpha^m$  of the range shown.

$r$	$\mathcal{C}$	$n_m$	$W$	$2S_T + 1$	BQN
0	–	–	1	7	–
1	{1}	1	5	5	$ I_\alpha^1  \leq 2$
2	{1}	2	6	3	$ I_\alpha^1  \leq \frac{3}{2}$
2	{2}	1	3	3	$ I_\alpha^2  \leq 1$
3	{1}	3	1	1	$ I_\alpha^1  \leq 1$
3	{1, 2}	1,1	3	1	$ I_\alpha^1  \leq 1,  I_\alpha^2  = 0$
3	{3}	1	1	1	$ I_\alpha^3  = 0$

Elements of the string motif serve as the template of the spinon motif of the same  $S_T$ -multiplet. Spinons are specified by their spin and momentum quantum numbers. The spinon interaction depends on the particle momenta and (in general) also on the particle spins. The unique  $XXX$  ground state for even  $N$  is the spinon vacuum. The ground state for odd  $N$  is fourfold degenerate and contains exactly one spinon. The total number  $N_s$  of spinon is restricted to be even (odd) for even (odd)  $N$  and can assume the values  $0 \leq N_s \leq N$ . Counting the spin-up spinons ( $N_+$ ) and spin-down spinons ( $N_-$ ) separately produces the relations

$$N_+ + N_- = N_s, \quad N_+ - N_- = 2M_z. \quad (38)$$

It is useful to introduce spinon orbitals associated with distinct spinon momentum quantum numbers  $m_i$ . The wave number of any  $XXX$  multiplet can be expressed in terms of the spinon orbital momenta as follows:

$$k = \left( \frac{\pi}{N} \sum_{j=1}^{N_s} m_j - \frac{N\pi}{2} \right) \text{mod}(2\pi). \quad (39)$$

The range of  $m_i$  depends on both  $N$  and  $N_s$ :

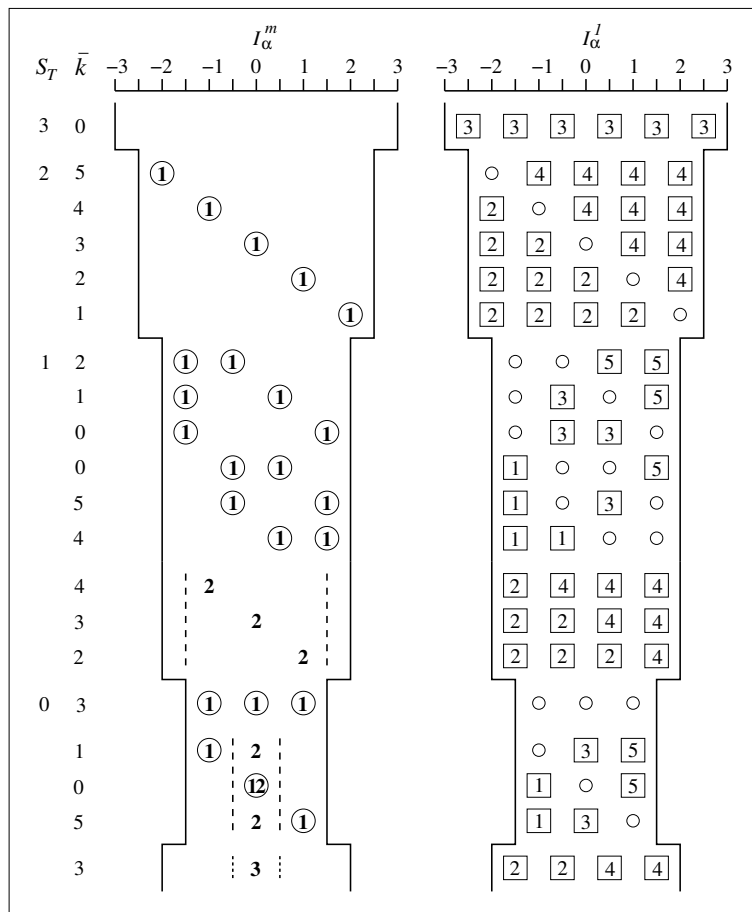

$$m_i = \frac{N_s}{2}, \frac{N_s}{2} + 2, \dots, N - \frac{N_s}{2}. \quad (40)$$

Thus, the number of available orbits to  $N_s$  spinons,  $N_{\text{orb}} = (N - N_s)/2 + 1$ , decreases by one for every two spinons added,  $\Delta N_{\text{orb}} = -\Delta N_s/2$ , which is one way of recognizing the semionic nature of spinon particles. The exact exclusion statistics of spinons is encoded in the number of ways  $N_+$  spin-up spinons and  $N_-$  spin-down spinons can be distributed among  $N_{\text{orb}}$  accessible orbitals. The spinon multiplicity expression [18],

$$W(N_+, N_-) = \prod_{\sigma=\pm} \binom{d_\sigma + N_\sigma - 1}{N_\sigma}, \quad d_\sigma = A_\sigma - \sum_{\sigma'=\pm} g_{\sigma\sigma'}(N_{\sigma'} - \delta_{\sigma\sigma'}), \quad (41)$$

$$A_\sigma = \frac{1}{2}(N + 1), \quad g_{\sigma\sigma'} = \frac{1}{2}, \quad (42)$$

is cast in the same general form as its string counterpart (35). Summation of  $W(N_+, N_-)$  over all the allowed values of  $N_\pm$  accounts for all  $2^N$  states.

**Figure 4.** Specification of all  $S_T$ -multiplets of the XXX model for  $N = 6$  in the string representation (left) and spinon representation (right). The quantum numbers  $S_T$  and  $\bar{k} \doteq Nk/2\pi$  of each multiplet are stated on the far left. The positions of the numbers  $m = 1, 2, 3$  and the vertical lines (left) mark the values of the  $I_\alpha^m$  and their range. The  $I_\alpha^1$ , emphasized by circles, are markers for the spinon configurations (right), where they are reproduced as small circles. Each square on the right represents a spinon. The set of squares is complementary to that of circles with the same range. The number  $m_i = 1, 2, \dots, 5$  inside each square marks the spinon orbital. The energy of each  $S_T$  multiplet is stated on the far right.

The complementary relationship between the string and spinon particles is reflected in their motifs. In figure 4 we show the string motif and spinon motif of all 20  $S_T$ -multiplets for  $N = 6$

side by side. The number of spinons contained in each eigenstate of a given  $S_T$ -multiplet is equal to the number of vacancies left by the 1-string BQN,  $I_\alpha^1$ , across the range (28). In figure 4 (right) we have marked the positions of the  $I_\alpha^1$  by circles and the vacancies by squares. The number inside each square denotes the orbital  $m_i$  to which every spinon belongs. The available orbitals depend on  $N_s$  via (40).

The rules for assigning spinons of particular momentum quantum numbers to orbitals must ensure (i) that the  $m_i$  reproduce, via (39), the wave number  $k$  already known via (27) and (ii) that the permissible spin orientations are consistent with the quantum number  $S_T$ . The allowed combinations of spinon orbitals are encoded in those  $S_T$ -multiplets that do not contain any strings with  $m > 1$ . Here the positions of the 1-strings, i. e. the circles in the spinon motifs, play the role of delimiters between successive spinon orbitals.

A spinon orbital with  $l_i$  spinons has an orbital spin  $S_i^{\text{orb}} = l_i/2$ ,  $i = 1, \dots, N_{\text{orb}}$ . If all  $N_s$  spinons are in the same orbital such as in the first two motifs (numbered from top to bottom) this spinon configuration represents a multiplet with  $S_T = S_i^{\text{orb}} = N_s/2$ . Any distribution of spinons into multiple orbitals represents more than one  $S_T$ -multiplet. The multiplets represented are determined via the decomposition of tensor products of orbital spins.

For example, if we have one spinon with  $m_i = 2$  and three spinons with  $m_i = 4$ , that decomposition reads  $\frac{1}{2} \otimes \frac{3}{2} = 2 \oplus 1$ . The associated multiplets with  $S_T = 2$  and  $S_T = 1$  are found in motifs three and thirteen, respectively. The configuration with two spinons in each of the same two orbital represents three  $S_T$ -multiplets according to  $1 \otimes 1 = 2 \oplus 1 \oplus 0$ . They are found in motifs four, fourteen, and twenty, respectively. The systematic application of these rules assigns a unique spinon momentum and spin content to every  $S_T$ -multiplet.

The energetic split of different  $S_T$ -multiplets associated with the same spinon momenta is caused by a coupling between orbital spins. In the Haldane-Shastry model, which has higher symmetry, that coupling is absent and these particular  $S_T$ -multiplets remain degenerate [27,28]. In the  $XX$  model, which has lower symmetry, even the  $S_T$ -multiplets split up energetically as will be discussed in section 3.3 [14].

The translation and reflection symmetries of  $\mathcal{H}_{XXZ}$  dictate that every state with wave number  $k$  can be transformed into a state with wave number  $2\pi - k$  and the same energy, implying that any state with  $k = 0, \pi$  is its own image. These transformation properties are reflected in the string motif ( $I_\alpha^m \rightarrow -I_\alpha^m$ ) and in the spinon motif ( $m_i \rightarrow N - m_i$ ) as is evident in figure 4.

### 3.2. Ising limit: stretched strings, domains, and solitons

In the following we describe three ways of generating the spectrum of the Ising chain, each producing a distinct set of quasiparticles with different exclusion statistics. We begin with the analysis of the string solutions of the BAE from section 2.1. To arrive at a non-divergent spectrum in the Ising limit of  $\mathcal{H}_{XXZ}$  we rescale the exchange coupling as follows:

$$\mathcal{H}_I \doteq \lim_{\Delta \rightarrow \infty} \Delta^{-1} \mathcal{H}_{XXZ} = J \sum_{l=1}^N S_l^z S_{l+1}^z. \quad (43)$$

The rescaled energy expression (5) of the Bethe ansatz in a raw form becomes

$$\frac{E - E_F}{J} = -r + \lim_{\Delta \rightarrow \infty} \sum_{i=1}^r \frac{\cos k_i}{\Delta}. \quad (44)$$

Evidently, real magnon momenta contribute only summarily to the energy, namely via the first term in (44). Non-vanishing terms  $\cos k_i/\Delta$  can only come from complex  $k_i$  with infinite imaginary parts.

We first track the highest-weight states of the  $S_T$ -multiplets from the  $XXX$  limit to the Ising limit. For these states, all solutions that are real at  $\Delta = 1$  stay real and all solutions that are complex at  $\Delta = 1$  have imaginary parts that diverge as  $\Delta \rightarrow \infty$ . The non-highest-weight states evolve far less uniformly. The additional rapidities, which are all equal to  $\pm\infty$  at  $\Delta = 1$ , become,

in general, finite and thus contribute to the energetic split of the  $S_T$ -multiplets. In some states, the extra  $z_i$  stay real, in other states they combine to form complex pairs. It appears that this transformation from real to complex rapidities takes place throughout the axial regime. Here we focus on the end product at  $\Delta = \infty$ , where the ferromagnetic domains in Ising product eigenstates become the natural quasiparticles.

Expanding the trigonometric BAE (22) of the axial regime about the Ising limit produces, in leading order, a set of linear BAE for the real parts of the rapidities,

$$\left( N - \sum_{m' \in \mathcal{C}} t_{mm'} n_{m'} \right) z_\alpha^m = 2\pi J_\alpha^m - \sum_{m' \in \mathcal{C}} t_{mm'} \sum_{\alpha'=1}^{n_{m'}} z_{\alpha'}^{m'}, \quad (45)$$

where the new set  $\{J_\alpha^m\}$  of BQN, related to the original set  $\{I_\alpha^m\}$  by a shift that depends on  $N$  and  $n_m$ , has the same range (28)

$$|J_\alpha^m| \leq \frac{1}{2} \left( N - 1 - \sum_{m' \in \mathcal{C}} t_{mm'} n_{m'} \right), \quad t_{mm'} \doteq 2\min(m, m') - \delta_{mm'}, \quad (46)$$

which guarantees the correct number of states from the highest-weight type. As the first step in the solution of the linear BAE (45) for these states we introduce the quantities

$$\zeta_m \doteq N - \sum_{m' \in \mathcal{C}} n_{m'} t_{mm'}, \quad J_m \doteq \sum_{\alpha=1}^{n_m} J_\alpha^m, \quad Z_m \doteq \sum_{\alpha=1}^{n_m} z_\alpha^m. \quad (47)$$

Thus, equations (45) summed over  $\alpha$  can be brought into the form

$$Z_m = 2\pi \frac{J_m}{\zeta_m} - \sum_{m' \in \mathcal{C}} \frac{n_{m'}}{\zeta_m} t_{mm'} Z_{m'} \quad (48)$$

with  $\zeta_m$  guaranteed to be positive. Equation (48) is solved by matrix inversion. Substitution of the solution  $Z_m$  into (45) yields the rapidities

$$z_\alpha^m = 2\pi \frac{J_\alpha^m}{\zeta_m} - \sum_{m' \in \mathcal{C}} \frac{t_{mm'}}{\zeta_m} Z_{m'}. \quad (49)$$

More explicit solutions in compact form for the situations where only 1-strings or only 2-strings are present read

$$z_\alpha^1 = \frac{2\pi}{N-r} J_\alpha^1 - \frac{2\pi}{N(N-r)} J_1, \quad \alpha = 1, \dots, r, \quad (50)$$

$$z_\alpha^2 = \frac{2\pi}{N-3r/2} J_\alpha^2 - \frac{6\pi}{N(N-3r/2)} J_2, \quad \alpha = 1, \dots, r/2. \quad (51)$$

If a single  $m$ -string with  $1 \leq m \leq N/2$  is present we have  $z_1^m = (2\pi/N) J_1^m$  with  $|J_1^m| \leq (N-2m)/2$ .

In figure 5 we have reproduced the BQN of all 20 highest-weight states for  $N = 6$  at  $\Delta = 1$  from figure 4 and have added the BQN for all 22 non-highest-weight states with  $M_z \geq 0$ . The additional  $I_\alpha^1$  of non-highest-weight states, obtained for  $\Delta = 1$  as described at the end of section 2.2, are located beyond the range of the  $I_\alpha^1$  for the highest-weight states (vertical lines).

The choice of the extra  $I_\alpha^1$  and the associated shift of the  $I_\alpha^m$  already present is not unique in most cases. Our choice was guided by the aim to avoid multiple  $I_\alpha^1$  of the same value and to restore the symmetry relations described at the end of section 3.1. For states with  $k = 0, \pi$ , which are their own images under the symmetry transformation, neither goal was fully achievable for  $N = 6$ . The  $I_\alpha^1$  configurations are asymmetric in several instances and two identical  $I_\alpha^1$  are unavoidable in one instance. These aesthetic flaws pose no problem for what follows.

To the right of each string motif in figure 5 we have added another motif in the shape of a ket. It identifies each string solution as tracked from  $\Delta = 1$  to  $\Delta = \infty$  with an Ising eigenstate

**Figure 5.** Specification of all  $XXX$  eigenstates with  $M_z \geq 0$  for  $N = 6$  in the string representation (two columns). The quantum numbers  $M_z$ ,  $S_T$  and  $\bar{k} \doteq Nk/2\pi$  of each state are stated on the left. The vertical lines indicate the range (28) of the  $I_\alpha^1$ . The positions of the numbers  $m = 1, 2, 3$  between the vertical lines represent the values of the  $I_\alpha^m$  for the highest-weight states (with  $M_z = S_T$ ). The additional BQN of the non-highest-weight states (with  $0 \leq M_z < S_T$ ) are all located outside. In the Ising limit each state evolves into a translationally invariant linear combination of Ising product states with domains of lengths as indicated on the far right in each column.

as composed of linear combinations of ferromagnetic domains. We have already introduced these domains in the context of figure 2. Here we use a notation conducive to linking Ising product eigenstates with obvious domain composition to Bethe eigenstates with specific string structure in the limit  $\Delta = \infty$ .

Let the set of  $\lambda$  product vectors, with  $r = N/2 - M_z$  flipped spins that are generated from one such state,  $|\sigma_1 \cdots \sigma_N\rangle$ , via translations, be represented by  $\{|\sigma_1 \cdots \sigma_N\rangle\}_\lambda$ . Let

$$\left\{ \underbrace{1 \cdots 1}_{\nu_1} \underbrace{2 \cdots 2}_{\nu_2} \underbrace{3 \cdots 3}_{\nu_3} \cdots \right\}_\Lambda \quad (52)$$

represent the set of  $\Lambda$  translationally invariant linear combinations of all product states that contain  $\nu_n$  domains of length  $n$  subject to the constraint  $\nu_1 + 2\nu_2 + 3\nu_3 + \cdots = r$ . Any set of the latter kind is constructed from one or several sets of the former kind with matching domain content. For  $N = 6$

there are seven sets of translationally invariant Ising eigenstates at  $M_z \geq 0$  thus constructed:

$$\{|0\rangle\}_1 \stackrel{l.c.}{\leftarrow} \{|\uparrow\uparrow\uparrow\uparrow\uparrow\uparrow\rangle\}_1; \quad \{|1\rangle\}_6 \stackrel{l.c.}{\leftarrow} \{|\uparrow\uparrow\uparrow\uparrow\downarrow\rangle\}_6; \quad \{|2\rangle\}_6 \stackrel{l.c.}{\leftarrow} \{|\uparrow\uparrow\uparrow\downarrow\downarrow\rangle\}_6; \quad (53a)$$

$$\{|11\rangle\}_9 \stackrel{l.c.}{\leftarrow} \{|\uparrow\uparrow\downarrow\uparrow\downarrow\rangle\}_6, \{|\uparrow\uparrow\downarrow\uparrow\downarrow\rangle\}_3; \quad \{|3\rangle\}_6 \stackrel{l.c.}{\leftarrow} \{|\uparrow\uparrow\downarrow\downarrow\downarrow\rangle\}_6; \quad (53b)$$

$$\{|12\rangle\}_{12} \stackrel{l.c.}{\leftarrow} \{|\uparrow\uparrow\downarrow\uparrow\downarrow\rangle\}_6, \{|\uparrow\uparrow\downarrow\uparrow\downarrow\rangle\}_6; \quad \{|111\rangle\}_2 \stackrel{l.c.}{\leftarrow} \{|\uparrow\downarrow\uparrow\uparrow\downarrow\rangle\}_2. \quad (53c)$$

In figure 5 we have identified each of these 42 states with a particular BAE solution in the limit  $\Delta \rightarrow \infty$ . The identification is straightforward for the highest-weight states. Each BQN  $I_\alpha^m$  represents exactly one domain of size  $\mu = m$ . However, the evolution of the non-highest-weight states between  $\Delta = 1$  and  $\Delta \rightarrow \infty$  is far less predictable. The extra BQN are all of the type  $I_\alpha^1$  at  $\Delta = 1$  and the associated rapidities are real and infinite. In some cases all extra rapidities stay real. The domain structure of these states is determined by the  $I_\alpha^m$  just as in highest-weight states.

However, for the majority of non-highest-weight states some of the rapidities that start out real at  $\Delta = 1$  turn into complex-conjugate pairs at  $\Delta > 1$  with imaginary parts that diverge as  $\Delta \rightarrow \infty$ . This metamorphosis necessitates a reconfiguration of the associated BQN (not shown in figure 5). Of the 22 non-highest-weight states for  $N = 6$  only six do not acquire additional complex rapidities between  $\Delta = 1$  and  $\Delta \rightarrow \infty$ , namely those states for which the string content encoded in the  $I_\alpha^m$  matches the domain content encoded in the ket.

The identification of the BAE solutions in the limit  $\Delta \rightarrow \infty$  with Ising eigenstates of specific domain content may be less certain in longer chains where states with different  $\{\nu_\mu\}$  but equal  $M_z$  are degenerate. That is the case for the two sets of states  $\{|13\rangle\}_{24}$  and  $\{|22\rangle\}_{12}$  in a chain with  $N = 8$  sites, for example. However, it seems reasonable to assume that this degeneracy is absent at  $\Delta < \infty$  in most if not all cases and thus guarantees that the BAE solutions have, in general, a unique domain content in the limit  $\Delta \rightarrow \infty$ . Even though the systematics of the transformation of some BAE solutions between  $\Delta = 1$  and  $\Delta \rightarrow \infty$  appears elusive at present, the systematics of the endproduct, namely the domain structure of the Ising spectrum for arbitrary  $N$ , is well known.

An Ising chain of length  $N$  can accommodate domains with  $\mu = 1, \dots, N-1$  consecutive flipped spins. Domains of size  $\mu$  are treated as distinct species of independent particles. The capacity for domains is restricted by the relation

$$\sum_{\mu=1}^{N-1} (\mu+1)\nu_\mu \leq N. \quad (54)$$

The total number of Ising eigenstates with domain content  $\{\nu_1, \nu_2, \dots\}$  is governed by a multiplicity expression somewhat similar to (35) yet different [26]:

$$W(\{\nu_\mu\}) = \frac{N}{N-r} \prod_{\mu=1}^{N-1} \binom{d_\mu + \nu_\mu - 1}{\nu_\mu}, \quad d_\mu = A_\mu - \sum_{\mu'=1}^{N-1} g_{\mu\mu'}(\nu_{\mu'} - \delta_{\mu\mu'}), \quad (55)$$

$$A_\mu = N - \mu, \quad g_{\mu\mu'} = \begin{cases} \mu', & \mu < \mu', \\ \mu' + 1, & \mu \geq \mu', \end{cases} \quad r = \sum_{\mu=1}^{N-1} \mu\nu_\mu. \quad (56)$$

The capacity of the system for domains is controlled by  $A_\mu$  and the statistical interaction between domains by  $g_{\mu\mu'}$ . All domains have the same energy,  $J$ . The statistical mechanics of domains for the Ising chain has been carried out exactly [26], reproducing familiar results.

In the context of figure 2 we have already qualitatively described the antiferromagnetic domain walls (solitons) that are complementary to the ferromagnetic domains. Among the four distinct bonds in the general product state  $|\sigma_1\sigma_2\cdots\sigma_N\rangle$ , the bonds  $\uparrow\uparrow, \downarrow\downarrow$  represent solitons with spin  $+1/2, -1/2$ , respectively, and  $\uparrow\downarrow, \downarrow\uparrow$  are vacuum bonds. Close-packed solitons with like spin orientation reside on successive bonds (e. g.  $\uparrow\uparrow\uparrow$ ), whereas close-packed solitons with opposite spin orientation are separated by one vacuum bond (e. g.  $\uparrow\uparrow\downarrow\downarrow$ ). Each of the seven sets of Ising eigenstates (53) contains a specific number of spin-up and spin-down solitons,  $(N_+, N_-) =$

$(6, 0), (4, 0), (3, 1), (2, 0), (2, 2), (1, 1), (0, 0)$ . All solitons have the same energy,  $J/2$ . The multiplicity expression for solitons [26],

$$W(N_+, N_-) = \frac{2N}{N - N_a} \prod_{\sigma=\pm} \binom{d_\sigma + N_\sigma - 1}{N_\sigma}, \quad d_\sigma = A_\sigma - \sum_{\sigma'=\pm} g_{\sigma\sigma'}(N_{\sigma'} - \delta_{\sigma\sigma'}), \quad (57)$$

$$A_\sigma = \frac{1}{2}(N - 1), \quad g_{\sigma\sigma'} = \frac{1}{2}, \quad N_a = N_+ + N_-, \quad (58)$$

is similar to expression (41) for spinons. Solitons and spinons are both semions but have different pseudovacua. Whereas the spinon vacuum was found to be unique, the soliton vacuum is twofold, consisting of the two product Néel states,  $|\uparrow\uparrow\uparrow \cdots \downarrow\rangle$  and  $|\downarrow\uparrow\downarrow \cdots \uparrow\rangle$  or linear combinations thereof. The soliton vacuum, like the spinon vacuum, is realized only in chains with even  $N$ .

### 3.3. XX limit: broken strings, fermions, and spinons

Here we investigate what happens to the highest-weight and non-highest-weight states of the  $S_T$ -multiplets in the presence of planar exchange anisotropy, particularly in the limit  $\Delta = 0$ . We have seen that in the axial regime there exists a tendency for real BAE solutions to become complex. As  $\Delta \rightarrow \infty$  all imaginary parts diverge, binding the magnons tightly into domains. In the planar regime, there exists a trend in the opposite direction. At  $\Delta = 0$  all BAE solutions can be regularized as stated in section 2.3, making all magnon momenta real. All strings with  $m > 1$  break up into 1-strings. The configurations allowed by the set (34) of BQN, which describe regularized solutions, produce the complete spectrum for arbitrary  $N$ .

In figure 6 we show the configurations of  $I_\alpha^1$  of all 42 eigenstates with  $M_z \geq 0$  at  $\Delta = 0$  for  $N = 6$  in the same sequence as the corresponding  $S_T$ -multiplet states at  $\Delta = 1$  have been listed in figure 5. All multiplet states at  $\Delta = 1$  that contain only 1-strings keep the same configuration at  $\Delta = 0$ . In the other states, all  $I_\alpha^1$  stay in the same position except the pair of  $I_\alpha^1$  that have identical values in figure 5. They are replaced in figure 6 by a pair of distinct  $I_\alpha^1$ . Furthermore, each  $I_\alpha^2$  in figure 5 is replaced by two  $I_\alpha^1$  in figure 6 and the one occurrence of a  $I_\alpha^3$  is replaced by three  $I_\alpha^1$ . Whereas the general rules for these substitutions still elude us, the constraints imposed by symmetry and conservation laws eliminate any ambiguity for the case  $N = 6$  shown here. The resulting configuration of  $I_\alpha^1$  produces, via (33), the exact configurations of Jordan-Wigner fermion momenta in a periodic chain [19,21]. The statistical mechanics of the regularized 1-strings is that of a system of free Jordan-Wigner fermions [20].

Each  $XX$  eigenstate thus identified by its composition of 1-strings has a unique composition of spinons. The rules for inferring the spinon motif from the string motif are consistent with the rules described in section 2.2 for the case  $\Delta = 1$  but there are some noteworthy differences. The lower rotational symmetry at  $\Delta = 0$ , which splits up the  $S_T$ -multiplet degeneracy, makes it possible to assign to each  $XX$  state not only a spinon configuration with unique momentum quantum numbers but also a unique spin orientation to the spinons in each orbital.

The spinon motif is encoded in the string motif of each state shown in figure 6 as described in the following. (i) Consider the vertical lines dividing the space of the  $I_\alpha^1$  into two domains, the inside and the outside, the latter wrapping around at  $\pm N/2$ . (ii) Every  $I_\alpha^1$ -vacancy (small circle) inside represents a spin-up spinon (marked by a square) and every  $I_\alpha^1$  ('1') outside represents a spin-down spinon (marked by a diamond). (iii) Any number of adjacent spinons in the motif are in the same orbital, i. e. have the same momentum quantum number  $m_i$  from the set (40). Two squares or diamonds that are separated by  $\ell$  consecutive '1's have spinon quantum numbers separated by  $2\ell$ . (iv) The spinon momentum quantum numbers are sorted in increasing order from the line on the left toward the right through the inside domain ( $m_i^+$ ) and toward the left with wrap-around through the outside domain ( $m_i^-$ ).

The spinon motif of figure 6 establishes the much needed link between spinon motif of the fermion representation at  $\Delta = 0$  introduced in [13,14] and the spinon motif of the string representation at  $\Delta = 1$  introduced in figure 5. Unlike the solitons at  $\Delta \rightarrow \infty$ , the spinons at  $\Delta = 0$  are not free. Nevertheless, an exact statistical mechanical analysis of spinons at  $\Delta = 0$  is possible [14].

**Figure 6.** Specification of all  $XX$  eigenstates with  $M_z \geq 0$  for  $N = 6$  in the string representation (two columns). The quantum numbers  $M_z$ , and  $\bar{k} \doteq Nk/2\pi$  of each state are stated on the left. Also shown on the left is the quantum number  $S_T$  of the multiplet at  $\Delta = 1$  from which the state evolved. The states are listed in the same sequence as those in figure 5. The positions of the '1' represent the values of the  $I_\alpha^I$  from (34) and constitute the motifs of the (broken) string configuration of the  $XX$  eigenstates. The motif of the complementary spinon configuration is marked by the squares (spin-up spinons) and diamonds (spin-down spinons) as explained in the text. The momentum quantum number  $m_i$  and the spin orientation  $\sigma_i$  of each spinon present in that state are given to the right of the dual string/spinon motif.

Away from the Ising limit, the solitons become interacting particles as well. They can be tracked all the way from  $\Delta \rightarrow \infty$  to  $\Delta = 0$ . A comparison between the spinon composition and soliton composition of the  $XX$  eigenstates can be found in [26].

#### 4. Conclusion

The long-established integrability of  $\mathcal{H}_{XXZ}$  imposes stringent constraints on the nature of the interaction between quasiparticles of any kind, reducing it, effectively, to two-body scattering events. As a consequence, these quasiparticles have infinite lifetimes and can be regarded as structural elements of the  $XXZ$  eigenstates. This makes it possible to systematically generate the complete spectrum from the pseudovacuum of one or the other set of quasiparticles.

In this work we have discussed two complementary sets of quasiparticles, one set being the basic elements of string solutions of the coordinate Bethe ansatz and the other the semionic spinons or solitons. Our focus has been on developing interlocking motifs for each set of quasiparticles for the purpose of tracking them across the axial and planar regimes of  $\mathcal{H}_{XXZ}$ . Starting from the symmetry point  $\Delta = 1$  in parameter space we have identified opposite trends, in the two regimes, in the evolution of string particles, which can be thought of as bound clusters of magnons. In

the axial regime, the strings show a tendency of increasing tightness in the binding within each cluster (rapidities with growing imaginary parts) and a tendency of merging clusters (real rapidities becoming complex). The endproduct at  $\Delta = \infty$  are ferromagnetic domains of flipped spins. In the planar regime, the strings appear to loosen up and break apart. At  $\Delta = 0$  it is possible to transform away all complex rapidities and with them any trace of magnon clustering. The free magnons behave like hard-core bosons or free fermions.

For  $J > 0$  the pseudovacuum of string particles is located at the top of the spectrum throughout the axial regime and then migrates down toward the center of the spectrum in the planar regime. The ground state (physical vacuum) of  $\mathcal{H}_{XXZ}$  is unique in the planar regime and twofold in the axial regime. It can be identified as the pseudovacuum of spinons or solitons, respectively. We have given detailed descriptions of spinons at  $\Delta = 0$  and  $\Delta = 1$  and of solitons at  $\Delta = \infty$ , including their relationship to the string particles. What remains to be investigated is the metamorphosis of the string particles between the special points  $\Delta = 0, 1, \infty$  in parameter space. This is work in progress. Of particular interest is an analysis of the transformations for which we have given here only qualitative descriptions and the impact of these transformations on the motifs such as displayed in figures 4–6 including the effects on the complementary spinon and soliton particles.

Отримано 3 травня 2009 р., в остаточному вигляді – 27 травня 2009 р.

Проаналізовано координатні Бете-анзатц розв'язки  $XXZ$  моделі для одновимірного спін-1/2 ланцюжка; у фокусі аналізу – статистичні властивості елементарних квазічастинок. Наголос зроблено на особливі випадки, відомі як  $XX$ ,  $XXX$  моделі чи модель Ізинга, для яких відбуваються істотні спрощення. Спектр  $XXZ$  моделі можна згенерувати з псевдовакууму як конфігурації з наборів квазічастинок з різними статистиками виключення. Ці набори є доповнючими у тому сенсі, що псевдовакуум одного набору містить максимальне число частинок з іншого набору. Струнні Бете-анзатц розв'язки для  $XXX$  моделі розгортаються по-різному у планарному і аксіальному режимах. У границі Ізинга вони стають ферромагнітними доменами з цілочисельною статистикою виключення. У  $XX$  границі вони розбиваються на жорсткосерцевинні бозони з (ефективною) ферміонною статистикою. Ми розрізняємо два набори квазічастинок зі спіном 1/2 і з дробовою статистикою: один набір (спітони) генерує  $XXZ$  спектр з єдиного критичного основного стану, що реалізується у планарному режимі; інший набір (солітони) генерує той самий спектр з двократно виродженого антиферромагнітно впорядкованого основного стану, що реалізується у аксіальному режимі. У границі Ізинга солітони стають антиферромагнітними доменними стінками.

**Ключові слова:**  $XXZ$  модель, підстановка Бете, струнна гіпотеза, дробова статистика, спітони, солітони
