Order-parameter fluctuations in the frustrated Heisenberg model on the square lattice

Shu Zhang and Gerhard Müller
Department of Physics, The University of Rhode Island, Kingston, Rhode Island 02881-0817

The \( T=0 \) dynamics of the two-dimensional spin-1/2 Heisenberg model with competing nearest-neighbor \((J_1)\) and next-nearest-neighbor \((J_2)\) interactions is explored via the recursion method, specifically the frequency-dependent fluctuations of the order parameters associated with some of the known or suspected ordering tendencies in this system, i.e., Néel, collinear, dimer, and chiral order. The results for the dynamic structure factors of the respective fluctuation operators show a strong indication of collinear order at \( J_2/J_1 \approx 0.6 \) and a potential for dimer order at \( 0.5 \leq J_2/J_1 \leq 0.6 \), whereas the chiral ordering tendency is observed to be considerably weaker.

\[ H = J_1 \sum_r S_r (S_{r+\hat{x}} + S_{r+\hat{y}}) + J_2 \sum_r S_r (S_{r+\hat{x}+\hat{y}} + S_{r+\hat{x}+\hat{y}}), \]

has been a prominent object of study in this context.\(^1\)

The Néel long-range order (LRO) present in the ground state of the \( nn \) model disappears at some critical coupling ratio, \( J_2/J_1 = 0.4 \), and is replaced, at sufficiently large \( J_2/J_1 \), by Néel LRO within each of the two \( nnn \) sublattices. The latter is preceded, at \( J_2/J_1 \geq 0.65 \), by collinear LRO, which breaks the (discrete) rotational symmetry of \( H \) on the lattice but not yet its (continuous) rotational symmetry in spin space. The Néel and collinear order parameters (OPs) are described by the operators

\[ O_{N} = \frac{1}{N} \sum_r (-1)^{r+\hat{x}} N_r, \quad O_{C} = \frac{1}{N} \sum_r C_r, \]

where \( N_r = S_r, C_r = S_r (S_{r+\hat{x}} + S_{r+\hat{y}} - S_{r+\hat{x}+\hat{y}} - S_{r+\hat{x}+\hat{y}}) \).

At intermediate coupling ratios, \( 0.4 \leq J_2/J_1 \leq 0.65 \), the Néel and collinear ordering tendencies keep each other at bay and thus make the frustrated ground state susceptible to different kinds of ordering potentialities. Dimer order,\(^2\,^3\) twist order,\(^4\) and chiral order\(^5\) have been proposed in this context. The dimer and chiral OPs considered here are defined by the following expressions in terms of spin operators:

\[ O_{D} = \frac{1}{N} \sum_r (-1)^{r+\hat{x}} D_r, \quad O_{\chi} = \frac{1}{N} \sum_r \chi_r, \]

where \( D_r = S_r S_{r+\hat{x}}, \quad \chi_r = Z_{r+\hat{x}+\hat{y}, r+\hat{x}+\hat{y}} - Z_{r+\hat{x}+\hat{y}, r+\hat{x}-\hat{y}}, \quad Z_{ijk} = i(S_{i} S_{j} - S_{k} S_{j} - S_{i} S_{k} + S_{i} S_{k}). \)

They probe the long-range phase coherence of singlets stacked in columns along the \( y \) axis and the handedness of the spin configuration on a plaquette, respectively, in the ground-state wave function \( |G\rangle \). Whether any one of these types of LRO is, in fact, realized, or whether a ground state with short-range correlations of the resonating-valence-bond type,\(^6\,^7\) for example, is stabilized, has not been determined for certain.

The absence or presence of a specific type of LRO determines whether the associated OP correlation function decays to zero or not. In the finite-cluster data, the relevant information on the asymptotic behavior is best captured by the expectation value of the squared OP. The problem here is to find a meaningful reference point for any enhancement in that quantity.\(^3\)

An alternative avenue to comparing the different ordering tendencies in the spin-frustrated ground state of (1) is to explore the dynamic (i.e., frequency-dependent) fluctuations of any proposed OP. The recursion method\(^8\) in conjunction with recently developed techniques of continued-fraction analysis\(^9\,^{10}\) is very suitable for that purpose. Here the dynamical information is derived from the finite-size ground-state wave function. No excited states have to be computed. This is an important advantage for the study of systems with complicated spectra and with potential OPs that have widely varying symmetry properties, as is the case here.

We investigate the fluctuations of the four OPs defined in (2) and (3) as they manifest themselves in the dynamic structure factors

\[ S_{\chi}(q, \omega) = \int_{-\infty}^{+\infty} dt e^{i\omega t} \langle F_{\chi}(t) F_{\chi}(0) \rangle, \]

where \( F_{\chi} = N^{-1/2} \sum_r e^{iq \cdot r} A_r \) is the fluctuation operator associated with a given OP, and \( A_r \) stands for \( N_r, C_r, D_r, \) or \( \chi_r \), as defined above.

The recursion algorithm in the present context is based on an orthogonal expansion of the wave function \( |\Psi_q(t)\rangle = F_q(-t) |G\rangle \). It produces (after some intermediate steps) a sequence of continued-fraction coefficients \( \Delta^\chi_q(q), \Delta^\chi_q(q), \ldots \) for the relaxation function

\[ c_{0}^{A}(q, z) = \frac{1}{z + \Delta^{A}_{q}(q) + \Delta^{A}_{q}(q) + \ldots} \]

\[ \Delta^{A}_{q}(q) = \Delta^{A}_{q}(q) + \Delta^{A}_{q}(q) + \ldots \]
which is the Laplace transform of the symmetrized correlation function \( \Re(F_4^A(t)F_4^A)/|F_4^A|^2 \). The \( T=0 \) dynamic structure factor is then obtained from (5) via

\[
S_{AA}(\mathbf{q}, \omega) = 4\langle F_4^A F_4^A \rangle \Theta(\omega) \lim_{\epsilon \to -0} \Re[c_0^A(\mathbf{q}, \epsilon - i\omega)],
\]

where \( \langle F_4^A F_4^A \rangle = S_{AA}(\mathbf{q}) \) is the integrated intensity.\(^{11}\)

All the results presented here are for clusters of \( N = 4 \times 4 \) sites with periodic boundary conditions. Extreme care must be exercised in separating finite-size effects from properties that reflect the physics of the infinite system. This distinction can be made with more confidence for coupling ratios \( J_2/J_1 \lesssim 0.7 \) than at \( J_2/J_1 > 0.7 \), where the gradual decoupling of the two \( nnn \) sublattices causes a crossover in the finite-size effects.

The Néel OP fluctuations are probed by the dynamic structure factor \( S_{NN}(\mathbf{q}, \omega) \) at the wave vector \( \mathbf{q} = (\pi, \pi) \). This quantity is shown in Fig. 1 for various coupling ratios. The presence of Néel LRO at \( J_2/J_1 = 0 \) implies that \( S_{NN}(\pi, \pi, \omega) \) is governed by a zero-frequency peak. Quantum fluctuations split the ground-state level for finite \( N \) and as \( N \) shrinks, and the integrated intensity continues to fade away quickly. As the two \( nnn \) sublattices begin to decouple, the system ceases to support well-defined Néel modes.

The dynamic structure factor for the collinear OP fluctuations, is shown in Fig. 2. At \( J_2/J_1 = 0 \), we observe a fairly sharp collinear mode at \( \omega/J_1 = 3.0 \). As the Néel ordering tendency weakens with increasing \( J_2/J_1 \), the collinear mode shifts to lower frequencies, while its line shape broadens considerably. The width reaches a maximum at \( J_2/J_1 = 0.4 \). Between here and \( J_2/J_1 = 0.55 \), where the competing dimer and chiral ordering tendencies are at their peak, the collinear modes moves to \( \omega = 0 \), and the integrated intensity more than triples in relation to its value at \( J_2/J_1 = 0 \). In the interval \( 0.55 \lesssim J_2/J_1 \lesssim 0.7 \), the function \( S_{CC}(0,0,\omega) \) transforms into a narrow peak position and line shape. Then the Néel OP fluctuations begin to change rapidly in two stages:

(i) Over the range \( 0.4 \lesssim J_2/J_1 \lesssim 0.6 \), the peak position moves to higher frequencies at an accelerated rate, the linewidth shrinks, and the integrated intensity (not shown) drops to 32% of its value at \( J_2/J_1 = 0 \). This signals the presence of some non-Néel type ordering tendency which supports well-defined Néel modes at increasingly high frequencies.

(ii) At \( J_2/J_1 > 0.6 \) the linewidth of \( S_{NN}(\pi, \pi, \omega) \) grows rapidly, while the peak position moves further up and the integrated intensity continues to fade away quickly. As the two \( nnn \) sublattices begin to decouple, the system ceases to support well-defined Néel modes.

The dynamic structure factor \( S_{CC}(0,0,\omega) \), which describes the collinear OP fluctuations, is shown in Fig. 2. At \( J_2/J_1 = 0 \), we observe a fairly sharp collinear mode at \( \omega/J_1 = 3.0 \). As the Néel ordering tendency weakens with increasing \( J_2/J_1 \), the collinear mode shifts to lower frequencies, while its line shape broadens considerably. The width reaches a maximum at \( J_2/J_1 = 0.4 \). Between here and \( J_2/J_1 = 0.55 \), where the competing dimer and chiral ordering tendencies are at their peak, the collinear modes moves to \( \omega = 0 \), and the integrated intensity more than triples in relation to its value at \( J_2/J_1 = 0 \). In the interval \( 0.55 \lesssim J_2/J_1 \lesssim 0.7 \), the function \( S_{CC}(0,0,\omega) \) transforms into a narrow peak position and line shape. Then the Néel OP fluctuations begin to change rapidly in two stages:

(i) Over the range \( 0.4 \lesssim J_2/J_1 \lesssim 0.6 \), the peak position moves to higher frequencies at an accelerated rate, the linewidth shrinks, and the integrated intensity (not shown) drops to 32% of its value at \( J_2/J_1 = 0 \). This signals the presence of some non-Néel type ordering tendency which supports well-defined Néel modes at increasingly high frequencies.

(ii) At \( J_2/J_1 > 0.6 \) the linewidth of \( S_{NN}(\pi, \pi, \omega) \) grows rapidly, while the peak position moves further up and the integrated intensity continues to fade away quickly. As the two \( nnn \) sublattices begin to decouple, the system ceases to support well-defined Néel modes.
central peak, and $S_{CC}(0,0)$ increases by another factor of \( \approx 1.6 \). This clearly reflects the onset of collinear LRO in the infinite system.

The dimer OP fluctuations as described by the dynamic structure factor $S_{DD}(\pi, 0, \omega)$ and shown in Fig. 3 resemble those of the collinear OP with respect to line shape and peak position for as long as the Ne\'el ordering tendency is perceptible in the ground state ($J_2/J_1 \leq 0.4$). Both modes become soft and very broad at $J_2/J_1 = 0.55$, but then they part company. While the collinear mode has been observed to transform into a high-intensity narrow central peak, the dimer mode, which has reached its maximum intensity here ($\approx 1.8$ times its value at $J_2/J_1 = 0$), broadens further and loses intensity very rapidly. It literally dissolves as the inter-sublattice correlations begin to weaken at $J_2/J_1 \approx 0.7$. Nevertheless, the softness of the dimer OP fluctuations at $J_2/J_1 = 0.55$ in the $4 \times 4$ cluster is consistent with dimer LRO in the infinite system.

The chiral OP fluctuations are based more significantly on intra-sublattice correlations than the dimer OP fluctuations and, therefore, evolve differently. This is illustrated in Fig. 4. At $J_2/J_1 = 0$ the dynamic structure factor $S_{\chi\chi}(0,0,\omega)$ exhibits a sharp mode at $\omega / J_1 \approx 3.8$. At $J_2/J_1 = 0.55$, the peak position has moved down to $\omega / J_1 \approx 1.6$, while the linewidth has increased only slightly, and the integrated intensity has grown to a maximum value of \( \approx 2.3 \) times its value at $J_2/J_1 = 0$. Then the peak position starts to move back out to higher frequencies, the line shape begins to broaden, but less so compared to that of the dimer fluctuations, and the integrated intensity drops rapidly. The minimum gap of the collinear mode is perhaps too large to be entirely attributable to a finite-size effect, which would indicate that the observed chiral ordering tendency does not turn into chiral LRO as $N \to \infty$.

This work was supported by NSF Grant No. DMR-93-12252 and by the NCSA at Urbana-Champaign.

11. A graph of the integrated intensity vs $J_3/J_1$ for each of the four types of OP fluctuations depicted in Figs. 1 through 4 can be found, e.g., in Ref. 1 (with different $N$-dependent factors).
