ABSTRACT—Umbrella species management offers a potential solution to the financial and logistical challenges of managing for the many declining species in early-successional forests, a habitat that is also critical for many mature and young forest songbird species during the post-fledging and post-breeding period. We investigated the movements of adult Eastern Towhees (*Pipilo erythrophthalmus*) during the post-fledging period in 4 km² landscapes managed for American Woodcock (*Scolopax minor*), a popular umbrella species candidate for young forest management. Home range size (mean = 2.8 ha, SE 0.33) did not differ during the post-fledging period between adult towhees inhabiting landscapes designated as high-likelihood (HL) or low-likelihood (LL) of woodcock use. Adults moved distances of ~37–47 m per day during the first 3 weeks of the post-fledging period and this did not differ between the 2 landscapes. In contrast, once their young became independent, adults moved longer distances in HL compared to LL landscapes (49.5 m [SE 2.9] and 36.7 m [SE 3.6], respectively) and these distances increased with home range size and patch size. Landscape features within 100 m of the towhee home range best explained variation in towhee movement distance. Young forest habitat was also the predominant forest type used by adult towhees caring for fledglings throughout the post-fledging period. These results suggest that early successional forest management for woodcock can provide effective breeding habitat for towhees, but likely at a smaller spatial scale than typically managed for woodcock. Received 31 March 2018. Accepted 27 November 2018.

Key words: adult movements, American Woodcock, Eastern Towhee, independence, post-fledging, umbrella species management

Land managers and conservationists frequently face the challenge of using limited resources while having to manage for multiple species. Umbrella species management can offer an efficient solution to such challenges because land management focused on a single “umbrella” species can simultaneously benefit many co-occurring species (Lambeck 1997, Simberloff 1998, Fleishman et al. 2001) while also elevating the funding potential and resource allocation for the focal species of interest (Andelman and Fagan 2000, Kellert 2012, Fourcade et al. 2017). Game bird species are popular candidates for umbrella species status because they are usually charismatic species that attract
opportunities for financial gains through hunting revenues, there are often established management histories and prescriptions, and there are usually potential benefits of this management for nongame species (Suter et al. 2002, Masse et al. 2015).

Most avian studies that assess habitat quality in areas principally managed for game species focus on songbird occupancy and density during the breeding period when males are territorial (Suter et al. 2002, Roberge and Angelstam 2004, Johnson 2007). Other studies on nontarget songbirds also measure nest success and survival of young (Herkert et al. 2003, Campbell et al. 2007, Chandler et al. 2009). Although the results of such studies can help determine whether certain land management techniques benefit these nontarget songbird species, the territory establishment and nesting period constitute an important but relatively small portion of a migratory songbird’s breeding cycle.

Recent work has focused on the post-fledging period because survival during this period often strongly influences population dynamics (Vega Rivera et al. 1998, Streby and Andersen 2011, Cox et al. 2014, Vernasco et al. 2018), and because movements and habitat use during the post-fledging period are often different than at other times of the annual cycle (Chandler et al. 2012, Burke et al. 2017).

Landscape-level factors may affect spatial movement, habitat use, and nest success in songbirds (Saab 1999, MacFaden and Capen 2002, Okada et al. 2017) and landscape-level features could lead to the different patterns of use or avoidance of certain managed areas at different life stages (Ahlering and Faaborg 2006, Fahrig 2013). Few studies of nontarget songbird species have characterized the spatial movements of adults during the post-fledging stage (Bayne and Hobson 2001, Vitz and Rodewald 2006). Even though adult survival rate is usually high during this time (Krementz et al. 2000, Sillett and Holmes 2002), there are potential changes in habitat use as young become more mobile and independent. This period constitutes a large portion of time that many migratory birds will spend in management areas and may influence predation risk or habitat selection (Vitz and Rodewald 2007, Streby 2016). During the post-fledging stage, adults are not anchored to a nest with immobile young that require frequent feedings, protection, and thermoregulation (van Overveld et al. 2017), and thus the effect of landscape-level factors on adult movement patterns and space use may be especially prominent during this stage with more independence (Bayne and Hobson 2001).

We studied the movement patterns and habitat use of adult Eastern Towhees (Pipilo erythrophthalmus) during the post-fledging period while they inhabited areas actively managed for American Woodcock (Scolopax minor). The loss of early successional forests throughout southern New England (Schlossberg and King 2007, Buffum et al. 2011) has been associated with the declines of popular upland game bird species such as Ruffed Grouse (Bonasa umbellus) and American Woodcock, as well as many nongame bird species (Askins 2001, King and Byers 2002). Early successional forests have been shown to be important for songbirds that inhabit mature forests during the nesting period, such as Ovenbird (Seiurus aurocapilla) and Wood Thrush (Hylocichla mustelina), which move to early successional forests during the post-fledging stage (Vega Rivera et al. 1998, Vitz and Rodewald 2010, Chandler et al. 2012). Early successional forest management in New England has focused on creating singing grounds, roosting fields, and nesting habitat for American Woodcock (hereafter, “woodcock”) via forest clearcuts and active brush-thinning and mowing operations (Williamson 2010, Masse et al. 2014). Previous research has identified woodcock as a good umbrella species
candidate for other early successional forest species (Bakermans et al. 2015, Masse et al. 2015), but little work has explored the impacts of this land management on the spatial ecology of songbirds within landscapes managed for woodcock.

The Eastern Towhee is a common but declining songbird in the Northeast US that inhabits scrub, edge, and young forest habitats (Greenlaw 2015). Eastern Towhees (hereafter, “towhee”) are an excellent species to study in habitat managed for woodcock because they are found during the breeding season predominantly in early-successional and young forests, occur simultaneously in the region with woodcock (Fleishman et al. 2001), and have demonstrated quick responses to management in previous studies (Yahner 2003). Towhee occurrence in managed shrublands in southern New England is influenced by certain landscape-level features such as overall shrubland area (Askins et al. 2007). However, no previous study has investigated the movement behavior of adult towhees during the post-fledging period when adults with fledglings are no longer tethered to their nest. Our primary objective was to compare home range size, habitat use, and movement patterns of adult towhees during the post-fledging period in state-managed areas that differed in their likelihood of use by woodcock (high- or low-likelihood of use). If woodcock serve as an effective umbrella species for towhees and other scrub-generalist songbirds, then we would expect towhees to positively respond to forest management targeted for woodcock.

**Methods**

**Study area**

All research was conducted within central and southern Rhode Island in Washington and Kent counties. Early successional forest management in these state-owned areas has focused in part on creating singing grounds, roosting fields, and nesting habitat for woodcock via forest clearcuts (Masse et al. 2014). The sites where we searched for and eventually tracked Eastern Towhees were the same state-managed young forests that were selected for a separate, simultaneous study on American Woodcock habitat selection (Brenner et al. 2019). We identified 6 landscapes (4 km²) of 2 types: high- and low-likelihood of use by woodcock. Each of these landscapes was centered on an area of managed early successional forest at which we confirmed woodcock breeding activity. These centers were recent (<15 yr) forest clearcuts 0.76–10 ha in size. In high-likelihood of woodcock use landscapes (hereafter, “HL landscapes”), there was more early successional forest/upland shrub, more hydric soils, and generally more mature deciduous or mixed forest (Masse et al. 2014, Brenner et al. 2019). In low-likelihood of woodcock use landscapes (hereafter, “LL landscapes”), there was more mature coniferous forest and relatively less early successional forest/upland shrub. This landscape size (4 km²) was chosen to match the recommended sizes for woodcock management in the Northeast (Williamson 2010, Masse et al. 2014). Our 3 HL landscapes were Great Swamp North (41°28′24″N, 71°34′19″W), Great Swamp South (41°27′10″N, 71°35′27″W), and Tillinghast Pond (41°38′55″N, 71°45′40″W). Our 3 LL landscapes were Big River East (41°38′19″N, 71°34′40″W), Arcadia: Midway (41°38′20″N, 71°34′39″W), and Arcadia: Pine Top (41°36′50″N, 71°46′26″W).

**Towhee netting and tracking**
We searched for territorial towhees from 25 May to 5 August 2016 and 2017 and limited our search to areas within the 6 focal landscapes that were young forest and upland scrub, including recent forest clearcuts, adjacent powerline right-of-ways, and areas with active brush thinning or mowing to maintain woodcock singing grounds. We opportunistically searched for towhee territories by walking within and along the edge (<50 m) of these managed young forest patches and looked for evidence of breeding activity (carrying nest material, carrying food, or caring for recently fledged young). When possible, we would locate nests and monitor nests until fledge or failure (Martin and Geupel 1993).

We used conspecific audio playback and mist nets to attract and capture territorial adult towhees or adults with nests or fledglings from 25 May to 5 August. We captured and tracked only 1 of the 2 adults that were caring for the same brood and did not target any particular sex during capture. After ageing, sexing, and taking basic morphometric measurements (Pyle 1997), we gave each individual a unique plastic color-band combination in addition to a standard USGS aluminum band. Advanced Telemetry Systems (Isanti, Michigan, USA) model A2400 VHF radio transmitter (weight = 0.71g, <2% body mass) were affixed to adult towhees using an elastic modified leg-loop harness design (Rappole and Tipton 1991), with size of harness based on the body mass of the bird (Naef-Daenzer 2007).

We used a 3-element Yagi antenna and ATS R2000 series receiver to track radiomarked adult towhees. Adults were located by first tracking individual signals with receivers to within 5–15 m of a bird. Observers would then visually search for and record each individual’s color bands and record the GPS location of each individual. Once located, a 20 min observation period followed to determine breeding stage, if the adults were caring for young, and the degree of parental care activity (Table 1). Some birds (n = 3) lost their transmitters before the end of the breeding season but were still raising young. These birds were tracked using vocalizations and color band resights, with the same 20 min observation protocol as if tracking by VHF.

We tracked adults from the first week after their young fledged from the nest (0–6 d after fledge) until at least 3 weeks after fledging or as long as the bird was on radio (23–54 d). We attempted to track each individual at least 3 times a week so we recorded at least 15 locations throughout the post-fledging period. We gathered one location per day for each individual to use in home range and movement analysis, and we stratified our sampling times each day to capture a majority of the active daytime hours for songbirds (0530 h – 1500 h EDT). Only adults that were able to successfully raise at least one towhee fledgling were included in the statistical analysis of home range size and movement patterns. We observed 2 instances of double brooding by adults in our study after they successfully raised at least one fledgling during their first nest attempt. Both failed on their subsequent nesting attempts. Although we tracked these individuals throughout the summer, we limited our spatial analysis to only those locations used before the second nest was initiated.

**Determining age of recently fledged young**

In cases where we discovered adults with young after the nestling period and during the first week (0–6 d) of fledging (14 of 31 individuals), we visually estimated the age of fledglings using plumage, locomotive, and behavioral cues (Table 1). These age estimates were based on the characteristics of known-age fledglings and previous work with
fledgling songbirds (Sullivan 1988, Kershner et al. 2004, White and Faaborg 2008, Burke et al. 2017). Adults that we began tracking with young that were older than one week after fledging (7+ d) or for which we were unable to obtain 15+ GPS locations were not used in home range or movement analysis. To determine changes in movement patterns over time, we categorized the age of fledglings into 4 broad stages: early-fledgling (0–6 d), mid-fledgling (7–13 d), late-fledgling (14–20 d), and independence (21+ d; Table 1). These stages captured the broad changes in fledgling development and changes in parental care during the approximately 20 d dependent period with young. Survival of young is relatively constant after 20 d (Cox et al. 2014) and we never observed adults accompanied by dependent young more than 21 d post-hatch. Any adults we captured and began tracking with young that did not clearly fit within these 4 stages were excluded from home range and movement analysis (n = 2).

**Statistical analysis**

We used kernel density methods (Worton 1989) within Geospatial Modeling Environment (Beyer 2013) to calculate diurnal post-fledgling home ranges (95% contour) for adult towhees. We specified a Gaussian kernel with likelihood bandwidth estimator as recommended in studies such as ours with a small number (<50) of locations per individual (Home and Garton 2006). For the home range and movement analyses, we gathered on average 21 points per individual (range: 16–31 points) for 31 adult towhees with accompanying fledgling(s). We used statewide land cover data (RIGIS 2012) in ArcGis 10.2 (ESRI, Redlands, California, USA) to estimate forest composition (% young forest/scrub, mature coniferous forest, mature deciduous forest, mixed forest, and grassland/agriculture) within a given landscape size (i.e., 100, 250, 500, and 1,120 m) as well as the size of young forest patches (i.e., the managed areas where we searched for adults). To determine the scope of movement covered by adults during the 4 different stages of fledgling development, we measured the distances between sequential points that occurred within the same fledgling development stage (mean distance between daily locations; Bayne and Hobson 2001). We considered this measurement an indicator of the extent of space use during the different stages of the post-fledging period.

We used general linear models to test the effects of landscape type, sex, and young forest patch size on post-fledgling home range size. We also used general linear models to determine the effect of the surrounding forest composition on home range size at 4 different landscape scales: the original 4 km² woodcock landscapes (1,120 m from the edge of the home range), and at 500, 250, and 100 m from the edge of the home range. We used linear mixed-effects models to determine if the distance per day traveled by adults during each of the 4 fledgling development stages depended on landscape type, sex, site, and year. We used the ID of each individual bird as a random effect to control for repeated measures, and Tukey post hoc testing using least-squared means to determine significance at α = 0.05 between groups at different stages. After determining that adult movements differed during the independence stage between birds in the 2 landscape types, we conducted 2 additional statistical analyses to discern what general breeding and landscape variables influenced the distances moved during this stage. We used general linear models to test the effect of woodcock landscape type and all combinations of sex, young forest patch size, and home range size on distance moved per day across the independence stage. We used general linear models to test the effects of
surrounding forest composition at 4 different landscape scales on the distances moved during the independence stage. Given that the predominant habitat used by adults with fledglings was young forest/scrub, we used chi-squared test ($\chi^2$) to compare proportions of adult locations in young forest between the 2 types of woodcock landscapes at each of the 4 fledgling development stages. All statistical testing was completed using R open-source software (version 3.3.2; www.r-project.org). Values are reported as means and SE. We used Akaike’s Information Criteria (AIC) and Akaike weights ($\omega_i$) to select the best model among competing models (Anderson et al. 2000).

Results
From 25 May to 5 August in 2016 and 2017, we captured, color banded, and affixed transmitters to 60 adult towhees. Of these, 31 adults (21 male, 10 female) provided a sufficient number of locations to be used in our analysis of home range size and habitat use during the post-fledging stage, and distance moved per day during each of the 4 stages of fledgling development. Nineteen of these birds were tracked in HL landscapes, and 12 birds were tracked in LL landscapes. Of the 29 adults captured but not used for home range and habitat use analysis, 10 adults successfully raised fledglings, but we either began tracking them after the first week of fledge, or we did not gather 15+ points throughout the season. Of the other 19 adults not used for home range or habitat use analysis, 10 adults were tracked but we could not confirm whether they successfully raised young to fledge or successfully nested at all, 8 adults attempted to nest but failed (sometimes in multiple attempts) during incubation, the nestling stage, or right before fledging, and one individual was depredated within one week of tracking.

Home range and scope of movements in different woodcock landscapes
Home range size of the 31 adults during the post-fledging period averaged 2.8 ha (SE 0.33, range: 0.78–8.06 ha). There was no difference in post-fledging home range size for towhees in HL landscapes (3.09 ha, SE 0.43) compared to LL landscapes (2.37 ha, SE 0.49, $F_{1,29} = 1.18$, $P = 0.285$; Fig. 1). All 11 models to explain home range size had poor fit ($R^2 \leq 0.122$) and none of these models was significant ($P \geq 0.134$).

The best model to explain the distances moved per day of adults during the post-fledging period included fledgling development stage and landscape type. During the first 3 stages of fledgling development, there were no significant differences in the daily movement distances of adult towhees in the HL vs. LL landscapes (early fledging: $t = 0.2$, $P = 0.858$; mid-fledging: $t = 0.9$, $P = 0.399$; late fledging: $t = 0.9$, $P = 0.375$; Fig. 2). However, during the independence stage, adult towhees in HL landscapes covered longer distances per day than adults in LL landscapes ($t = 2.1$, $P = 0.045$; Fig. 2). The 3 top models ($\leq 2 \Delta$AIC) to explain the differences in movement distances during the independence stage of fledgling development always included home range size and landscape type ($R^2 = 0.413$, $F_{2,28} = 11.6$, $P \leq 0.001$; Table 2A), with patch size and sex included in 2 of these 3 models ($R^2 = 0.388$ [Patch and Sex] $R^2 = 0.387$ [Sex]; Table 2A). Distances were longer in HL compared to LL landscapes and increased with home range size, patch size, and for males. The highest-ranked model that incorporated landscape composition features was forest composition within 100 m of the post-fledging home range (Table 2B), although this model did not explain much of the variation in movement distance of adult towhees ($R^2 = 0.141$, $F_{5,25} = 2.0$, $P = 0.119$).
Most (54.5%) of the adult towhee locations collected throughout the post-fledging period occurred within young forest/scrub, with mature upland forest types (26.2%) and grasslands/fields (14.6%) accounting for the majority of the remaining habitat types. Adult towhees in HL landscapes compared to LL landscapes used marginally less young forest/scrub during the early-fledgling stage (51.7% in HL and 69.3% in LL, $\chi^2 = 2.9$, df = 1, $P = 0.086$) and mid-fledgling stage (43% in HL and 60% in LL, $\chi^2 = 3.4$, df = 1, $P = 0.063$). There was no difference in young forest/scrub use between adults in different landscape types during the late-fledgling (55% in HL and 60% in LL, $\chi^2 = 0.1$, df = 1, $P = 0.705$) or independence stage (55.4% in HL and 60% in LL, $\chi^2 = 0.5$, df = 1, $P = 0.467$).

**Discussion**

**Potential impact of umbrella species management for woodcock on adult towhees during the post-fledging period**

Overall, adult towhee home range size and distance moved per day prior to independence were similar between landscapes that differed in their suitability for woodcock. These results combined with the fact that young forest habitat was the predominant forest type used by adult towhees caring for fledglings, and that this same young forest habitat was created in the region to promote woodcock use, suggest that a broad mix of early-successional forest management can provide breeding and post-breeding habitat for towhees.

Woodcock require several different forest types and habitats during the breeding and post-breeding period in order to thrive. Woodcock use clearcuts and open fields for displaying and roosting, young forest and scrub for nesting, and moist soils with enough vegetative cover for safe diurnal feeding (Dessecker and McAuley 2001, Masse et al. 2014). Many aspects of the movements and habitat use of woodcock differ from that of towhees, although they clearly both require early-successional forest during the breeding season. Recommended minimum patch size for young forest songbirds such as towhees in the Northeast is 0.6–1 ha (Askins et al. 2007, Schlossberg and King 2007), which was consistent with the smallest early-successional forest patch size (0.76 ha) used by breeding towhees in our study. Thus, both the size and type of habitat needed for breeding towhees was available in the state-owned areas managed for woodcock that we studied. Adequate vegetation to provide nesting cover, protection for fledged young from predators, and adequate forage (Stoleson 2013, Greenlaw 2015) are necessary for scrub-generalist towhees to successfully raise young, and this vegetation was available in both landscapes managed for woodcock and resulted in similar post-fledgling home range sizes and movements. However, we need better information about how such land management affects productivity (i.e., nest success, clutch and brood size), recruitment, and survival of towhees before we can determine if focused management for woodcock also enhances towhee populations.

**Behavioral shift for adult towhees once young reached independence**

We did not observe significant changes in the scope of adult movements while they were still caring for their fledglings, even as young became more mobile in the mid- and late-fledgling stages (Fig. 2). However, when parental care ceased during the independence stage, adults in HL landscapes traveled across greater distances per day than adults in LL
landscapes (Fig. 2) Adult towhees consistently used primarily young-forest habitat throughout the post-fledging and independence stages. Previous work with adult Ovenbirds during the post-fledging period also noted a lack of difference in home range size and movements between birds in different landscapes, but did observe differences in space use between adults with and without young (Bayne and Hobson 2001). We observed all adults essentially cease parental care about 20 d after their young fledged. This independence period is likely an important time for adults that have successfully raised young because it is when post-breeding adults must focus on individual maintenance and recovery of condition before migration (Vitz and Rodewald 2007).

Adult towhees that inhabited HL landscapes moved over longer distances during the independence stage (21+ d after fledge) than those inhabiting LL landscapes. The extent of these movements during the independence stage was most related to home range size, size of young-forest patches, and forest composition within 100 m of the towhee home range. Previous research on shrubland bird communities in the state also noted the positive impact of habitat features such as wetland shrubland within 100 m of territorial males (Buffum and McKinney 2014), further indicating that landscape impacts on the movement of songbirds in early-successional forests likely occurs at a spatial scale much smaller than that typically managed for woodcock.

**Woodcock as an umbrella species**

Our results suggest that management for woodcock singing and nesting grounds in forested landscapes in southern New England can provide breeding and post-breeding habitat for towhees, mainly through the creation of new early-successional forest, shrub, and dense understory habitat. However, forest management for woodcock in the northeastern United States typically occurs at a larger (at least 4 km$^2$) spatial scale (Williamson 2010, Masse et al. 2014) than what we found was used by towhees during the post-fledging and independence stages of their life history. Adult towhee post-fledging home range sizes did not differ between HL and LL landscapes, whereas male woodcock behavior differed in these same 4 km$^2$ landscapes in a previous study (Brenner et al. 2019). Thus, while both species utilize early-successional forests, they are likely responding to habitat features at different spatial scales (Kramer et al. 2019).

Towhees are part of a particular guild of generalist shrubland songbirds that forage primarily on the ground and rely upon forest understory (Greenlaw 2015, Langlois 2017). However, other declining early-successional forest/shrubland songbirds have more specific habitat requirements than the relatively ubiquitous towhee (DeGraaf and Yamasaki 2003, Leuenberger et al. 2017) and have been shown to respond differently to landscape- and local-scale features than the towhee (Askins et al. 2007, 2012). A particular forest management strategy focused on woodcock that benefits some early-successional species in one region may not apply to other early-successional species in a different region. Thus, the ecology and habitat requirements of nontarget songbird species must be well understood before broad management recommendations are applied across taxa (Hale and Swearer 2017, Kramer et al. 2019). Studies that combine occupancy, reproductive, and spatial information for focal songbird species are needed to successfully refine umbrella species management in order to successfully manage at the appropriate spatial scale for the highest number of species.
Acknowledgments
This study was funded through grants from the Rhode Island Agricultural Experiment Station, the Rhode Island Department of Environmental Management via the USFWS Wildlife and Sport Fisheries Restoration to RI project W23R (Job 1-12), and the URI Department of Natural Resource Science, College of Environmental and Life Sciences. All birds were captured under master bander permit #22923 from the US Geological Survey Bird Banding Laboratory, and all research activities were approved by the University of Rhode Island Institutional Animal Care and Use Committee (#AN10-02-017). We would like to thank Brian Tefft for his logistical support and Scott Comings and The Nature Conservancy for granting land access. We would like to thank L. Douglas, M. Moniz, K. Blackmon, E. Gonzalez, R. Healey, and K. Tillinghast for their support in the field. We also thank Olivia DaRugna for banding support, fieldwork, and assistance with fledgling aging characteristics. This is contribution number 5472 of the Rhode Island Agricultural Experiment Station.

Table 1. General characteristics (i.e., appearance, mobility) of young Eastern Towhees and the parental care behavior of adult towhees during the 4 stages of the post-fledging period.

<table>
<thead>
<tr>
<th>Fledgling stage</th>
<th>Appearance of young</th>
<th>Mobility of young</th>
<th>Parental care by adult towhees</th>
</tr>
</thead>
<tbody>
<tr>
<td>Early-fledgling (0–6 days)</td>
<td>Plumage is part downy, spotted on chest, drab colors. Minimal tail visible. Large, soft yellow bill.</td>
<td>Big legs with developing flight feathers. Cannot fly above 2–3 m, mostly limited to ground or short jumps.</td>
<td>Adults very attentive. Feeding frequently, become very agitated when observer near fledgling(s).</td>
</tr>
<tr>
<td>Mid-fledgling (7–13 days)</td>
<td>Plumage is developing, but still mostly spotted appearance with some richer brown tones developing. Some tail visible. Outer bill edges still noticeably yellow.</td>
<td>Able to make decent lateral flights to escape (5–15 m). Movement is more fluid. Not able to reach canopy or high perches.</td>
<td>Adults still feed regularly and remain near young. Less agitation when observers near, but still will call frequently.</td>
</tr>
<tr>
<td>Late-fledgling (14–20 days)</td>
<td>Spotting mostly limited to face and replaced by streaking on body. Wings and tail developing adult colors (brown or black). Full tail.</td>
<td>Sustained flights and confident movers on the ground. Able to reach high perches and canopy.</td>
<td>Adults will still travel with young, but limited feedings and limited agitation when observers are near.</td>
</tr>
<tr>
<td>Independence (21+ days)</td>
<td>Body plumage buff with faint streaks, but wings and tail fully adult in color. Head usually buff color.</td>
<td>Fully capable in all movements. Begins to call like adult after week 4</td>
<td>Little to no parental care. Adults will occasionally move with young.</td>
</tr>
</tbody>
</table>

Table 2. (A) Highest-ranked general breeding models to explain the movement distances of adult Eastern Towhees during the independence stage of the post-fledging period. Variables included American Woodcock likelihood of use landscape (amwoLand), young forest patch size (patch), sex, and overall home range size (HR) during the post-fledging period. (B) Highest-ranked landscape composition models to explain the movement distances of adult towhees during the independence stage of the post-fledging period. Variables included percent young forest/shrub (PctShrub), percent mature coniferous forest (PctCon), percent mature deciduous forest (PctDec), percent mixed forest (PctMix), and percent grassland/agriculture (PctGrass) at 4 different landscape scales.

Figure 1. Home range size for adult Eastern Towhees during the post-fledging stage. Circles represent individual home range sizes for 19 towhees in high-likelihood of American Woodcock use landscapes. Triangles represent individual home range sizes for 12 towhees in low-likelihood of woodcock use landscapes.
Figure 2. Daily movement distances (mean ± SE) of adult towhees during 4 different fledgling development stages. Circles represent Eastern Towhees in high-likelihood of American Woodcock use landscapes, and triangles represent towhees in low-likelihood of woodcock use landscapes (* $P < 0.05$).
