Abstract

The secondary cell walls of tracheary elements and fibers are rich in cellulose microfibrils that are helically oriented and laterally aggregated. Support cells within the leaf midribs of mosses deposit cellulose-rich secondary cell walls, but their biosynthesis and microfibril organization have not been examined. Although the Cellulose Synthase (CESA) gene families of mosses and seed plants diversified independently, CESA knockout analysis in the moss Physcomitrella patens revealed parallels in CESA functional specialization of Arabidopsis and P. patens, with roles for both sub-functionalization and neo-functionalization. The similarities include regulatory uncoupling of the CESAs that synthesize primary and secondary cell walls, a requirement for two or more functionally distinct CESA isoforms for secondary cell wall synthesis, interchangeability of some primary and secondary CESAs, and some CESA redundancy. The cellulose-deficient midribs of ppcesa3/8 knockouts provided negative controls for structural characterization of stereid secondary cell walls in wild type P. patens. Sum frequency generation spectra collected from midribs were consistent with cellulose microfibril aggregation, and polarization microscopy revealed helical microfibril orientation only in wild type leaves. Thus, stereid secondary walls are structurally distinct from primary cell walls, and they share structural characteristics with the secondary walls of tracheary elements and fibers. We propose a mechanism for convergent evolution of secondary walls in which deposition of aggregated and helically oriented microfibrils is coupled to rapid and highly localized cellulose synthesis enabled by regulatory uncoupling from primary wall synthesis.

Introduction

In vascular plants, cellulose is a major component of both primary cell walls that are deposited during cell expansion and secondary cell walls that are deposited after expansion has ceased (Carpita and McCann 2000). Secondary cell walls of water-conducting tracheary elements and supportive fibers are rich in cellulose with microfibrils arranged in helices that vary in angle according to developmental stage and environmental conditions (Barnett and Bonham 2004). Secondary cell wall microfibrils are also more aggregated than those of primary cell walls (Donaldson 2007; Fernandes et al. 2011; Thomas et al. 2014). Recently, Sum Frequency Generation (SFG) spectroscopy has been used to compare the mesoscale structure of cellulose microfibrils in primary and secondary cell walls. Both high cellulose content and microfibril aggregation contribute to a strong secondary cell wall signature in SFG spectra of mature angiosperm tissues (Barnette et al. 2012; Lee et al. 2014; Park et al. 2013).

Cellulose microfibrils are synthesized by cellulose synthase (CESA) proteins that function together as cellulose synthesis complexes (CSCs) in the plasma membrane (Delmer 1999; Kimura et al. 1999).
Recent analyses of CSC and microfibril structure indicate that the rosette CSCs of land plants most likely contain 18 CESA subunits (Fernandes et al. 2011; Jarvis 2013; Newman et al. 2013; Nixon et al. 2016; Oehme et al. 2015; Thomas et al. 2014; Vandavasi et al. 2016) in a 1:1:1 ratio (Gonneau et al. 2014; Hill et al. 2014). Seed plants have six phylogenetic and functional classes of CESA proteins, three required for primary cell wall synthesis (Desprez et al. 2007; Persson et al. 2007) and three required for synthesis of the lignified secondary cell walls of tracheary elements and fibers (Taylor et al. 2003). Mutation of any of the secondary CESAs results in a distinctive irregular xylem phenotype characterized by collapsed xylem tracheary elements and weak stems (Taylor et al. 2004). The secondary cell wall CESAs of Arabidopsis are regulated by master regulator NAC domain transcription factors that also activate genes required for the synthesis of other secondary cell wall components, such as xylan and lignin (Schuetz et al. 2013; Yang and Wang 2016; Zhong and Ye 2015).

The moss Physcomitrella patens (Hedw.) B. S. G. has seven CESA genes (Goss et al. 2012; Roberts and Bushoven 2007). Phylogenetic analysis has revealed that the P. patens CESAs do not cluster with the six CESA clades shared by seed plants (Roberts and Bushoven 2007). Like other mosses, P. patens lacks the lignified secondary cell walls that are characteristic of vascular plant tracheary elements and fibers. However, mosses do have support cells (stereids) with thick unlignified cell walls (Kenrick and Crane 1997) and water-conducting cells (hydroids) that have thin cell walls and undergo programmed cell death like tracheary elements (Hebant 1977). Although the stereid cell walls of P. patens are known to contain cellulose (Berry et al. 2016), the mesoscale structure has not been examined. Only one of the seven P. patens CESAs has been characterized functionally. When PpCESA5 was disrupted, gametophore buds failed to develop into leafy gametophores, instead forming irregular cell clumps. The associated disruption of cell expansion and cell division are consistent with an underlying defect in primary cell wall deposition (Goss et al. 2012). Recently it was shown that PpCESA3 expression is regulated by the NAC transcription factor PpVNS7, along with thickening of stereid cell walls (Xu et al. 2014).

Here we show that PpCESA3 and PpCESA8 function in the deposition of stereid cell walls in the gametophore leaf midribs of P. patens and are sub-functionalized with respect to PpCESA5. We also used polarization microscopy and SFG to reveal similarities in the mesoscale organization of the microfibrils synthesized by PpCESA3 and PpCESA8 and those in the secondary cell walls of vascular plants. Finally, we propose a mechanism through which uncoupling of primary and secondary CESA regulation played a role in independent evolution of secondary cell walls with aggregated, helically arranged cellulose microfibrils in the moss and seed plant lineages.
Results

PpCESA3 and PpCESA8 function in secondary cell wall deposition

Cellulose synthase genes PpCESA3 and PpCESA8 were independently knocked out by homologous recombination in an effort to examine their roles in development and cell wall biosynthesis in P. patens. Stable antibiotic resistant lines generated by transforming wild type P. patens with CESA3KO or CESA8KO vectors were tested for integration of the vector and deletion of the target gene by PCR (Fig. S1). Integration was verified for five ppcesa8KO lines recovered from two different transformations, line 8KO5B from a transformation of the GD06 wild type line and lines 8KO4C, 8KO5C, 8KO7C and 8KO10C from a transformation of the GD11 wild type line (Fig. S1). Integration was verified for three ppcesa3KO lines recovered from a single transformation of GD11 and three double ppcesa3/8KO lines recovered from a single transformation of the ppcesa8KO5B line with the CESA3KO vector (Fig. S1).

The GD06 and GD11 lines are from independent selfings of the same haploid wild type line, as described in Materials and Methods.

The colonies that developed from wild type and KOs consisted of protonemal filaments and leafy gametophores (Fig. 1). Whereas wild type, ppcesa3KO, and ppcesa8KO gametophores grew vertically, the gametophores on ppcesa3/8KO colonies were unable to support themselves and adopted a horizontal orientation. Superficially ppcesa3/8KO colonies appeared to produce fewer gametophores (Fig. 1), but dissection revealed similar numbers of horizontal gametophores that had been overgrown by protonemal filaments. Thus, PpCESA3 and PpCESA8 are not required for gametophore initiation or morphogenesis, but they appear to contribute to structural support.

When examined with polarized light microscopy, the wild type gametophore leaves exhibited strong cell wall birefringence in the midribs and margins (Fig. 1). In contrast, the leaves produced by ppcesa3/8KOs lacked strong birefringence in these cells, consistent with reduced crystalline cellulose content. The ppcesa3KO leaves appeared similar to wild type leaves (Fig. 1) and ppcesa8KO leaves had an intermediate phenotype. Staining with the fluorescent cellulose binding dye Pontamine Fast Scarlet (S4B) (Anderson et al. 2010) produced similar results with strong fluorescence in the midribs of wild type and ppcesa3KO leaves, weak fluorescence in ppcesa3/8KO leaves, and intermediate fluorescence in ppcesa8KO leaves (Fig. 1).

Cellulose Binding Module (CBM) 3a provides a third method for detecting cellulose and can be used to probe thin sections (Blake et al. 2006). In sections from fully expanded wild type leaves, the walls of the lamina cells were labeled relatively weakly with CBM3a, whereas the thickened cell walls of the central
midrib and bundle sheath cells were strongly labeled (Fig. 1). The same was true for *ppcesa3*KO leaves. However, midrib and bundle sheath cell labeling was nearly absent in *ppcesa3/8*KO and diminished in *ppcesa8*KO (Fig. 1) compared to wild type and *ppcesa3*KO. Differential interference contrast microscopy of the same sections showed enhanced contrast in wild type and *ppcesa3*KO midribs (Fig. 1). Partial cell collapse occurred during embedding in *ppcesa3/8*KO leaves (Fig. 1).

The cellulose content of the leaf midribs in wild type and single and double *ppcesa*KO mutants was quantified by measuring the intensity of S4B fluorescence. Statistical analysis confirmed that the S4B fluorescence was significantly reduced in double KOs, but not in *ppcesa3*KOs (Fig. 2). The intermediate phenotype of the *ppcesa8*KOs was confirmed and shown to be significantly different from both wild type and the double KOs (Fig. 2). Updegraff analysis showed that cellulose content of cell walls from whole *ppcesa3/8*KO gametophores (mean±S.E. of three genetic lines = 33.8±0.034%) was reduced significantly (p = 0.004) compared to wild type (GD06, mean±S.E. of three independent cultures = 60.1±0.030%).

To confirm that the observed *ppcesa3/8*KO phenotype was due to the absence of PpCESA3 and PpCESA8, the selection cassette was removed from *ppcesa3/8*KO-86 by Cre-mediated recombination of flanking *lox-p* sites (Vidali et al. 2010) to allow transformation with vectors that drive expression of PpCESA3 or PpCESA8 with their native promoters (Fig. S2). Stable antibiotic resistant lines selected for the presence of numerous erect gametophores were examined with polarization microscopy (Fig. S2). For the transformation with *proCESA8::CESA8*, 13 lines were examined, 6 of these had strong midrib birefringence, and the first 3 were used for further analysis. For the transformation with *proCESA3::CESA3*, the first three lines examined had strong midrib birefringence and were used for further analysis. S4B staining confirmed that expression of PpCESA8 or PpCESA3 rescued the defects in cellulose deposition in the leaf midribs of the double *ppcesa3/8*KO (Fig. 2). Lines from the transformation with *proCESA8::CESA8* were expected to be restored to the wild type phenotype because *ppcesa3*KO, which also expresses PpCESA8 under control of the *PpCESA8* promoter, showed no defects in cellulose deposition in the leaf midrib. All three *proCESA8::CESA8* lines had significantly stronger S4B fluorescence than *ppcesa8*KO. This demonstrates substantial restoration of the phenotype, although fluorescence was still significantly weaker than the wild type (Fig. 2). Two lines from a transformation with *proCESA3::CESA3* (3R29 and 3R52) were not significantly different from *ppcesa8*KO-5B, which is expected since they both lack *PpCESA8* and express *PpCESA3* under control of the *PpCESA3* promoter. In the third line (3R45) fluorescence was restored to wild type levels (Fig. 2). Y-axis scales differ between experiments due to the use of different exposure time settings.
Secondary cell wall microfibrils are helically oriented and laterally aggregated

A first order retardation plate was used with polarized light microscopy to determine the optical sign, and thus the cellulose microfibril orientation, of wild type and *ppcesa3/8KO* midrib cell walls (Fig. 3). In mature wild type leaves, the larger bundle sheath-like cells that surround the central stereids showed blue addition colors when oriented parallel to the major axis of the plate and yellow subtraction colors when oriented perpendicular to the major axis (Fig. 3), indicating that the net orientation of positively birefringent cellulose microfibrils is longitudinal. In contrast, the walls of the smaller central stereids were colorless when oriented parallel or perpendicular to the major axis (Fig. 3). However, when oriented at 45° to the retardation plate, these cells showed alternating bands of blue and yellow (Fig. 3), indicating that the microfibrils in their walls are helical with an angle near 45°. The central midrib cells of developing wild type leaves showed a transition from colorless to blue to yellow along the apical to basal developmental gradient when the midrib was oriented parallel to the major axis of the plate (Fig. 3). This indicates that the microfibril orientation changes from transverse to longitudinal and then to helical as the cells mature. In contrast, the central midrib stereids of mature *ppcesa3/8KO* leaves had blue addition colors when oriented parallel to the major axis, yellow subtraction colors when oriented perpendicular to the major axis, and no interference color when oriented at 45° to the retardation plate indicating that microfibrils are longitudinal, rather than helical. Developing *ppcesa3/8KO* leaves had no longitudinal gradient in interference colors (Fig. 3).

The walls of midrib cells were examined by transmission electron microscopy in ultrathin sections of chemically fixed gametophore leaves. Despite the reduced cellulose content detected by other means, the walls of midrib cells were thickened compared to walls of adjacent lamina cells in all *ppcesa*KOs, as well as wild type leaves (Fig. 4). When we attempted to prepare specimens by high pressure freezing and freeze-substitution, the leaves fractured in a plane parallel to the midrib. This resulted in a loss of midrib cells and precluded examination of midrib cell walls in these specimens. We were able to examine the lamina and margin cells of freeze-substituted leaves in wild type and two lines of each mutant. The walls of these cells appeared similar between wild type, and single and double *ppcesa*KOs (Fig. S3). However, measurements revealed that lamina cell external walls, i.e. those facing the external environment, were thinner in *ppcesa*KOs (Fig. S4).

The mesoscale organization of cellulose in the midribs of wild type, *ppcesa3/8KO*, and *ppcesa8KO* leaves was examined using a broadband SFG microscope (Lee et al. 2016). Because it detects only non-centrosymmetric ordering of functional groups, SFG provides a means of analyzing cellulose in intact cell walls with relatively little interference from matrix components (Barnette et al. 2011). For each genotype,
full SFG spectra collected from three different locations along the midribs of each of three different leaves were averaged (Fig. 5). The sampling depth of the SFG microscope for cellulosic samples is 20-25 μm (Lee et al. 2016). Given that the thickness of turgid leaves is about 50-60 μm at the midrib and that they likely collapse to less than half their thickness when dried, we conclude that most of the leaf thickness contributes to the SFG signal. In spectra collected from the wild type, a strong peak at 2944 cm\(^{-1}\), which is characteristic of secondary cell walls, was observed in the CH/CH\(_2\) stretch region along with a 3320 cm\(^{-1}\) peak in the OH stretch region. In contrast, the spectra collected from ppcesa3/8KO and ppcesa8KO midribs had weaker peak intensity overall with a broad CH/CH\(_2\) stretch peak centered around 2910 cm\(^{-1}\). Compared to ppcesa3/8KO, the spectra from ppcesa8KO midribs had a weak signal at 2963 cm\(^{-1}\) that was absent in spectra collected from ppcesa3/8KO midribs. A scan across a wild type leaf shows that the 2944 cm\(^{-1}\) signal is associated with the midrib and was not observed in the cells of the lamina (Fig. 5). Equivalent scans of ppcesa3/8KO and ppcesa8KO leaves confirm the absence of a strong 2944 cm\(^{-1}\) peak from the midribs of these mutants (Fig. 5).

**PpCESA proteins are functionally specialized**

Based on the ppcesa3KO, ppcesa8KO, and ppcesa3/8KO phenotypes, PpCESA3 and PpCESA8 appear to be partially redundant. To determine whether the relative strengths of these phenotypes are related to gene expression levels, we used reverse transcription quantitative PCR to measure the expression of PpCESA3 and PpCESA8 in the wild type and mutants. In the ppcesa3KOs, PpCESA8 was significantly upregulated compared to wild type (Fig. 6), providing a possible explanation for the lack of a mutant phenotype in these lines. In contrast, PpCESA3 was not significantly upregulated in the ppcesa8KOs compared to wild type, potentially explaining the intermediate phenotype in these mutants.

ppcesa3KOs, ppcesa8KOs and ppcesa3/8KOs were tested for changes in rhizoid and caulonema development to determine whether developmental defects were restricted to the gametophores. When cultured on medium containing auxin, all lines produced the expected leafless gametophores with numerous rhizoids (Fig. S5), indicating no defects in rhizoid development in any of the KOs. Caulonema produced by colonies grown in the dark on vertically oriented plates were all negatively gravitropic (Fig. S6). Although appearance of the caulonema varied among experiments, those produced by KOs were always similar to control wild type within the same experiment. Caulonemal length was not significantly different between ppcesa3/8KOs and wild type (Table 1).

To determine whether other PpCESAs are functionally interchangeable with PpCESA3 and PpCESA8, we tested for rescue of ppcesa3/8KO-86lox by various PpCESAs driven by the PpCESA8 promoter.

Polarization microscopy screening of at least 21 and up to 27 stably transformed lines for each vector
revealed little or no midrib birefringence for the proCESA8::CESA4, proCESA8::CESA7 and proCESA8::CESA10 lines and moderate to strong midrib birefringence for 92% and 78% of the proCESA8::CESA3 and proCESA8::CESA5 lines, respectively. Quantitative analysis of S4B staining (Fig. 7) confirmed that the ppcesa3/8KO phenotype was partially rescued by proCESA8::CESA3 (3 out of 3 lines) and proCESA8::CESA5 (2 out of 3 lines) as we observed for proCESA8::CESA8 (Fig. 2). However, the proCESA8::CESA4, proCESA8::CESA7 and proCESA8::CESA10 vectors showed no rescue (Fig. 7). Western blot analysis confirmed that PpCESA proteins were expressed in all lines except proCESA8::CESA4-11 and proCESA8::CESA5-7 (Fig. S7). PpCESA6 differs from PpCESA7 by only 2 amino acids and was not tested. Although expressed with the same promoter, protein accumulation varies among the different transgenic lines (Fig. S7). Similar differences in protein accumulation may also explain variation in the extent of rescue by the proCESA3::CESA3 and proCESA8::CESA8 vector (Fig. 2).

Finally, we examined ppcesa4/10KOs and ppcesa6/7KOs produced for another study to determine whether they phenocopy the ppcesa3/8KO phenotype. Genotype verification for these lines is presented in Fig. S8 and Fig. S9. The ppcesa4/10KOs showed slight, but significant reduction in midrib S4B fluorescence. However, for ppcesa6/7KOs the reduction was substantial and significant (Fig. 7), showing the PpCESA6/7 and PpCESA3/8 have non-redundant roles in secondary cell wall deposition in leaf midrib cells.

Discussion

PpCESA3 and PpCESA8 function redundantly in cellulose deposition in stereid secondary cell walls.

Targeted knockout of PpCESA3 and PpCESA8 blocked deposition of cellulose in the thick walls of stereid cells as indicated by 1) reduction of the strong birefringence associated with the midribs in ppcesa3/8KOs, 2) reduction in the midrib fluorescence of ppcesa3/8KO leaves stained with S4B, 3) lack of CBM3a labeling of sections from ppcesa3/8KO leaf midribs (Fig. 1), and 4) reduction in ppcesa3/8KO gametophore cell wall cellulose content as measured by Updegraff assay. Evidence that knockout of PpCESA3 and PpCESA8 is responsible for the observed phenotype includes consistency of the phenotype in three independent KOs and restoration of cellulose deposition in the midribs by transformation of ppcesa3/8KO with vectors driving expression of PpCESA3 or PpCESA8 (Fig. 2). Whereas we detected no reduction in midrib cellulose in ppcesa3KO, the phenotypes of ppcesa8KOs were intermediate between wild type and ppcesa3/8KO (Fig. 2). This, combined with the observations that only PpCESA8 is up-regulated to compensate for loss of its paralog (Fig. 6) and expression of PpCESA3 under control of
its native promoter only partially restores the wild type phenotype (Fig. 2), are consistent with the hypothesis that the PpCESA3 and PpCESA8 proteins are functionally interchangeable and that a dosage effect is responsible for the ppcesa8KO phenotype. The formation of morphologically normal gametophores in ppcesa3/8KOs (Fig. 1) indicates that PpCESA3 and PpCESA8 serve a different role in development than PpCESA5, which supports normal cell division and cell expansion required for gametophore development (Goss et al. 2012). It is possible that PpCESA3 and PpCESA8 contribute to primary cell wall deposition since ppcesa3/8KO lamina cells had thinner external walls (Fig. S4) and tended to collapse during embedding (Fig. 1). Alternatively, PpCESA3 and PpCESA8 may contribute to secondary thickening of lamina cell walls after they stop expanding.

**CESA evolution in both P. patens and Arabidopsis involve sub-functionalization and neo-functionalization.**

There are many parallels in the evolution of the *P. patens* and Arabidopsis CESA families. In both species, different CESAs are responsible for primary and secondary cell wall deposition. In Arabidopsis, the secondary CESAs are AtCESA4, -7 and -8 (Taylor et al. 2003) and primary CESAs are AtCESA1,-3, and members of the 6-like group (Desprez et al. 2007; Persson et al. 2007). In *P. patens*, midrib secondary cell wall synthesis involves PpCESA3, -6, -7 and -8, whereas gametophore primary cell wall synthesis requires PpCESA5 (Goss et al. 2012). At least some primary CESAs can substitute for secondary CESAs and vice versa in both species. In Arabidopsis, *AtCESA3pro::AtCESA7* partially rescues *atacesa3*, and *AtCESA8pro::AtCESA1* partially rescues *atacesa8* (Carroll et al. 2012). In *P. patens*, *PpCESA8pro::PpCESA5* rescues *ppcesa3/8KO*. This indicates that the CESA division of labor for primary and secondary cell wall deposition in vascular plants and mosses is due at least in part to sub-functionalization. However, neo-functionalization has also occurred in both species, resulting in the requirement for two or more non-interchangeable CESA isoforms for secondary cell wall biosynthesis. In Arabidopsis, *atacesa4*, *atacesa7*, and *atacesa8* null mutants share a phenotype (Taylor et al. 2000) that cannot be complemented by expressing one of the other secondary AtCESAs with the promoter for the missing isoform (Kumar et al. 2016). Likewise in *P. patens*, *ppcesa3/8KO* and *ppcesa6/7KO* share the same phenotype and *ppcesa3/8KO* is not complemented by *PpCESA8pro::PpCESA7*. Studies are ongoing to determine whether the secondary PpCESAs physically interact to form a CSC, as has been shown for the secondary AtCESAs (Taylor et al. 2003; Timmers et al. 2009). Finally, the CESA families of both species show some redundancy. In Arabidopsis the 6-like CESAs (AtCESA2, -5, -6 and -9) are partially redundant (Persson et al. 2007), as are *PpCESA3* and *-8* in *P. patens*. PpCESA6 and -7 differ by only three amino acids and the genes that encode them appear to be redundant (Wise et al. 2011).
A recent study has shown that secondary cell wall deposition, including CESA expression, is regulated by NAC transcription factors in both *P. patens* and Arabidopsis (Xu et al. 2014). Three *P. patens* NAC genes, *PpVNS1*, *PpVNS6*, and *PpVNS7*, were preferentially expressed in leaf midribs and *ppvns1/ppvns6/ppvns7* KOs were defective in stereid development. Overexpression of *PpVNS7* activated *PpCESA3* (Xu et al. 2014). Phylogenetic analyses of NACs place eight *PpVNS* proteins within the clade that has variously been named subfamily NAC-c (Shen et al. 2009), subfamily Ic (Zhu et al. 2012), or the VNS group (Xu et al. 2014), and also includes the Arabidopsis vascular-related NACs VND6 (ANAC101), VND7 (ANAC030), NST1 (ANAC043), NST2 (ANAC066) and NST3/SND1 (ANAC012).

However, the three *PpVNS* genes that regulate stereid development cluster with five other *P. patens* genes implicated in other processes, whereas the angiosperm genes cluster in clades that include members from divergent species (Xu et al. 2014). This is similar to CESA phylogenies, in which *P. patens* proteins are excluded from the clades that comprise each of the six functionally distinct seed plant CESAs (Kumar et al. 2016; Roberts and Bushoven 2007; Yin et al. 2009) and indicates that CESA sub-functionalization occurred independently in mosses and seed plants.

**Secondary cell wall microfibrillar texture is similar in mosses and vascular plants.**

In vascular plants, both water conducting tracheary elements and supportive fibers are characterized by helical (Barnett and Bonham 2004) and aggregated (Donaldson 2007; Fernandes et al. 2011; Thomas et al. 2014) cellulose microfibrils. The midribs of *P. patens* leaves include hydroid cells that transport water and stereid cells that provide support, but only the stereids have thick cell walls (Xu et al. 2014). With highly reduced cellulose in their stereid secondary cell walls, *ppcesa3/8* KOs provided a negative control for structural characterization of secondary cell walls in wild type *P. patens*. A sharp SFG CH/CH₂ stretch peak at 2944 cm⁻¹ is characteristic of angiosperm secondary cell walls (Park et al. 2013) and extensive empirical testing has shown that this spectral feature is attributable to lateral microfibril aggregation (Lee et al. 2014). The 2944 cm⁻¹ peak was also present in SFG spectra of wild type *P. patens* midribs. In contrast, the spectra of *ppcesa3/8* KO leaf midribs lacked the 2944 cm⁻¹ peak and instead had a broad peak between 2800 and 3000 cm⁻¹, which is characteristic of primary cell walls and other samples lacking aggregated microfibrils (Lee et al. 2014; Park et al. 2013). This suggests that lateral aggregation of microfibrils is a common feature of the secondary cell walls of moss stereids and vascular plant tracheary elements and fibers. Polarization microscopy with a first order retardation plate revealed that the microfibrils in the stereid cell walls are deposited in a helical pattern, as observed in secondary cell walls of tracheary elements and fibers (Barnett and Bonham 2004). Although deficient in cellulose, the stereid cell walls of *ppcesa3/8* KOs were thickened, indicating that secondary cell wall synthesis involves deposition of non-cellulosic components, which proceeded in the absence of cellulose deposition. This
has also been observed in developing tracheary elements treated with cellulose synthesis inhibitors (Taylor et al. 1992). Thus, stereid cell walls share structural characteristics with the cell walls of tracheary elements and fibers.

**Mosses and vascular plants have acquired similar secondary cell walls through convergent evolution.**

Thick, cellulose-rich secondary cell walls provide added support for aerial organs of mosses and vascular plants alike. Within these cell walls, the lateral aggregation and helical orientation of the microfibrils contributes to their strength and resiliency. Although cortical microtubules play an important role in cellulose microfibril orientation, oriented cellulose deposition can occur in the absence of cortical microtubules, and it has previously been suggested that aggregation and helical orientation of microfibrils in secondary walls is a consequence of high CSC density during rapid cellulose deposition (Emons and Mulder 2000; Lindeboom et al. 2008). Regulation at the level of CSC secretion was emphasized in this model (Emons and Mulder 2000), but CSC density can potentially be regulated at the level of transcription.

Rapid cellulose synthesis during secondary cell wall deposition in specific cell types requires precise temporal and spatial regulation of CESA expression that is distinct from the regulatory requirements for primary cell wall synthesis. We suggest that these distinct regulatory needs were met through the evolution of independent regulatory control of primary and secondary CESAs by sub-functionalization in both mosses and seed plants. In seed plants, phylogenetic analysis shows that the first divergence of the CESA family separated the genes that encode the primary and secondary CESAs and was followed by independent diversification within each group (Roberts et al. 2012). This, along with evidence that some primary CESAs are interchangeable with secondary CESAs (Carroll et al. 2012), indicates that sub-functionalization was an early event in the evolution of the seed plant CESA family. In *P. patens*, the genes that encode secondary PpCESA3 and PpCESA8 and primary PpCESA5 are also sub-functionalized and therefore specialized, although they encode interchangeable proteins.

Several lines of evidence indicate that the capacity to deposit a secondary cell wall evolved independently in mosses and seed plants. Structural and paleobotanical evidence suggests that the support and water-conducting cells of bryophytes and vascular plants are not homologous (Carafa et al. 2005; Ligrone et al. 2002). Phylogenetic evidence indicates that the primary and secondary CESAs diversified independently in mosses and seed plants (Kumar et al. 2016; Roberts and Bushoven 2007; Yin et al. 2009) and, as explained above, so did the NAC transcription factors that regulate the secondary CESAs. There are even examples of convergent evolution of secondary cell walls within the angiosperm lineage. Cotton fiber
secondary cell walls are synthesized by the same CESAs that are responsible for secondary cell wall deposition in tracheary elements and fibers (Haigler et al. 2012), whereas the secondary cell walls of epidermal trichomes are synthesized by the primary CESAs (Betancur et al. 2011). These observations are consistent with independent evolutionary origins for secondary cell walls in different land plant lineages and different cell types within angiosperm lineages.

Taken together, these data indicate that CESA duplication, followed by adoption of regulatory elements within the secondary CESA promoters that enable control by NAC transcription factors, occurred independently in mosses and vascular plants. The resulting uncoupling of the secondary CESAs from the regulatory constraints associated with primary cell wall deposition, along with a mechanistic linkage between CESA expression and microfibril texture as well as selection for strength and resiliency, may have contributed to the capacity of different plants to synthesize cellulose-rich secondary cell walls with similar microfibrillar textures.

Materials and methods

Vector construction

All primer pairs are shown in Table S1, along with annealing temperatures used for PCR. Amplification programs for Taq Polymerase (New England Biolabs, Ipswich, MA, USA) consisted of a 3 min denaturation at 94°C; 35 cycles of 15 s at 94°C, 30 s at the annealing temperature, and 1 min/kbp at 72°C. Amplification programs for Phusion Polymerase (New England Biolabs) consisted of a 30 s denaturation at 98°C; 35 cycles of 7 s at 98°C, 7 s at the annealing temperature, and 30 s/kbp at 72°C.

To construct the CESA8KO vector, a 3’ homologous region was amplified from *P. patens* genomic DNA with primers 174JB and 193JB using Taq DNA polymerase, cut with SalI and BspD1, and cloned into the Sall/BstBI site of pBHSNR (gift of Didier Schaefer, University of Neuchâtel). The resulting plasmid was cut with KasI and NsiI to accept the KasI/NsiI fragment of a 5’ homologous region amplified from *P. patens* genomic DNA with primers 203JB and 185JB (Table S1). The CESA8KO vector was cut with EcoRI and NsiI for transformation into wild type *P. patens*. The CESA3KO, CESA4KO, CESA6/7KO, and CESA10KO vectors were constructed using Gateway Multisite Pro cloning (Invitrogen, Grand Island, NY, USA) as described previously (Roberts et al. 2011). Flanking sequences 5’ and 3’ of the coding regions were amplified with appropriate primer pairs (Table S1) using Phusion DNA polymerase (New England Biolabs) and cloned into pDONR 221 P1-P4 and pDONR 221 P3-P2, respectively, using BP Clonase II (Invitrogen). Similarly, an *nph* selection cassette was amplified from pMBL6 (gift of Jesse Machuka, University of Leeds) cloned into pDONR 221 P3r-P4r. All entry clones were sequence-
verified. For vectors conferring hygromycin resistance, entry clones with flanking sequences in pDONR 221 P1-P4 and pDONR 221 P3-P2 were inserted into BHSNRG (Roberts et al. 2011). For vectors conferring G418 resistance, entry clones with flanking sequences in pDONR 221 P1-P4 and pDONR 221 P3-P2 were linked with the entry clone containing the *nph* selection cassette and inserted into pGEM-gate (Vidali et al. 2009) using LR Clonase II Plus (Invitrogen). The vectors in BHSNRG or pGEM-gate were cut with BsrGI for transformation into wild type or mutant *P. patens* lines.

Expression vectors for HA-tagged PpCESAs under control of *PpCESA* promoters were constructed using Gateway Multisite Pro cloning (Invitrogen). The *PpCESA4* (DQ902545), *PpCESA5* (DQ902546), *PpCESA7* (DQ160224) and *PpCESA8* (DQ902549) coding sequences were amplified from cDNA clones pdp21409, pdp24095, pdp38142 and pdp39044 (RIKEN BioResource Center, Tsukuba, Ibaraki JP), respectively, using forward primers containing a single hemagglutinin (HA) tag and appropriate reverse primers (Table S1) and cloned into pDONR 221 P5-P2 using BP Clonase II (Invitrogen). The *PpCESA3* (XP_001753310) and *PpCESA10* (XP_001776974) coding sequences were similarly amplified from expression vectors. pDONR 221 P1-P5r entry clones containing approximately 2 kB of sequence upstream of the *PpCESA3* or *PpCESA8* start codon (Tran and Roberts 2016), were linked to the sequence verified entry clones containing the *HA-PpCESA* coding sequences and inserted into pSi3(TH)GW (Tran and Roberts 2016) using LR Clonase II Plus (Invitrogen). These vectors target the expression cassettes to the intergenic 108 locus, which can be disrupted with no effect on phenotype (Schaefer and Zryd 1997). Rescue vectors were cut with Swal for transformation into a *P. patens ppcesa3/8KO* line from which the *hph* resistance cassette had been removed (see below).

**Culture and transformation of *P. patens***

Wild type *P. patens* lines (haploid) derived from the sequenced Gransden strain (Rensing et al. 2008) by selfing and propagation from a single spore in 2006 (GD06) or 2011 (GD11) were gifts of Pierre-Francois Perroud, Washington University. Wild type and transformed *P. patens* lines were cultured on basal medium supplemented with ammonium tartrate (BCDAT) as described previously (Roberts et al. 2011). Protoplasts were prepared and transformed as described previously (Roberts et al. 2011). Stable transformants were selected with 50 μg mL\(^{-1}\) G418 (CESA3KO vector) or 15 μg mL\(^{-1}\) hygromycin (CESA8KO and complementation vectors). The *hph* selection cassette was removed from *ppces3/ppcesa8KO* by transforming protoplasts with NLS-Cre-Zeo (Vidali et al. 2010) selecting for 7 d on BCDAT plates containing 50 μg mL\(^{-1}\) zeocin, replica plating zeocin resistant colonies on BCDAT with and without 15 μg mL\(^{-1}\) hygromycin, and recovering hygromycin-sensitive colonies. Protein expression
was tested by western blot analysis as described previously (Scavuzzo-Duggan et al. 2015) in selected
lines transformed with HA-PpCESA expression vectors.

**Genotype analysis**

For PCR screening, DNA was extracted as described previously (Roberts et al. 2011) and 2.5 μL samples
were subjected to 35 cycles of amplification (45 s at 94°C, 45 s at the annealing temperature shown in
Table S1, 1 min/kbp at 72°C) with PAQ5000 DNA polymerase (Agilent Technologies, http://www.home.agilent.com/) in 25 μL reactions. Primers used to test for target integration, target-gene
disruption, and selection cassette excision are listed in Table S1.

**Phenotype analysis**

Cell wall birefringence of unfixed leaves mounted in water was examined using an Olympus BHS
compound microscope with D Plan-Apo UV 10X/0.4, 20X/0.7, and 40X/0.85 objectives, and polarizer
and circular-polarizing analyzer, with and without a first order retardation plate (Olympus, Center Valley,
PA, USA). Images were captured with a Leica DFC310FX digital camera with Leica Application Suite
software, version 4.2.0 (Leica Microsystems Inc., Buffalo Grove, IL, USA) with manual exposure under
identical conditions.

For direct fluorescent labeling of cellulose, whole gametophores (3 per line) dissected from colonies
grown for four weeks on solid BCDAT medium were dipped in 100% acetone for 5 sec to permeabilize
the cuticle, rinsed in phosphate buffered saline (PBS), incubated in PBS containing 0.01 mg/ml S4B
(Anderson et al. 2010) for 30 min, and rinsed in PBS. All fully expanded leaves (12-20) were cut from
each gametophore and mounted in PBS. Fluorescence images of each leaf, centered on the brightest part
of the midrib, were captured using a Zeiss Axio Imager M2 with 43HE DsRed filter set, Plan-Neofluar
20X/0.5 objective, AxioCam MR R3 camera, and Zen Blue software, version 1.1.2.0 (Carl Zeiss
Microscopy, Jena, Germany) under identical conditions using manual exposure. The midrib in each image
was selected manually (Fig. S10) and average pixel intensity was measured using ImageJ, Fiji version
(Schindelin et al. 2012). For comparison of KO genotypes to the wild type, three independent lines of each KO
genotype (n=3) and two independent wild type lines (GD06 and GD11, n=2) were sampled in triplicate.
For analysis of rescue lines, three independent explants were sampled for each genetic line (n=3).

For affinity cytochemistry of cellulose, gametophores dissected from colonies grown for two weeks on
BCDAT medium were fixed and embedded in LR White resin (Polysciences, Inc., Warrington, PA, USA)
as described previously (Kulkarni et al. 2012). Sections (1 μm) were mounted and labeled with CBM3a as
described previously (Berry et al. 2016). Images were captured with a Zeiss Axio Imager M2 with 38
Green Fluorescent Protein filter set, EC Plan-Neofluar 40X/0.75 objective, AxioCam MR R3 camera, and Zen Blue software, version 1.1.2.0 (Carl Zeiss Microscopy) under identical conditions using manual exposure. Fluorescence and polarization images were not altered after capture. Bright field and differential interference contrast images were captured using automatic exposure and some images used for illustrative purposes were adjusted for uniformity using the color balance and exposure functions in Photoshop, version CS6 (Adobe Systems, San Jose CA, USA).

ppcesa3KOs, ppcesa8KOs, and ppcesa3/8KOs were tested for changes in caulonema gravitropism and rhizoid development as described previously (Roberts et al. 2011). Images were captured using a Leica M165FC stereomicroscope with Leica DFC310FX camera and Leica Application Suite software, version 4.2.0 (Leica Microsystems Inc.). Caulonema length for each colony was measured as the distance from the edge of the colony to tip of the longest caulonema filament using Leica Application Suite software.

Cell wall analysis

Alcohol insoluble residue (AIR) was prepared from gametophores dissected from 8-10 4-week-old explants of P. patens wild type (three samples from independent cultures) and ppcesa3/8KO (samples from three independent lines) cultured on BCDAT medium. Tissue was ground in liquid nitrogen and extracted three times, 30 min each, with 70% (v/v) ethanol and once with 100% ethanol and the residue was dried under vacuum. The AIR (~1 mg) was weighed to 0.001 mg and mixed with 1 mL of acetic acid:water:nitric acid (8:2:1, v/v) in screw-cap vials and the suspension was heated in a boiling water bath for 30 min (Updegraff 1969). After cooling, the tubes were centrifuged at 16,900 x g for 5 min and the supernatant discarded. The pellet was resuspended in 2 mL of deionized water, centrifuged, and the supernatant was discarded. The washing step was repeated at least 10 more times until the supernatant was neutralized and the pellet was resuspended in 1 mL of water. The amount of cellulose remaining after hydrolysis was quantified by sulfuric acid assay (Albalasmeh et al. 2013) with glucose as the standard. Briefly, 100 µL of hydrolysate (six technical replicates per sample) was diluted to 1 mL with water in a glass tube, 3 mL of concentrated sulfuric acid was added, and samples were vortexed for 30 s and chilled on ice for 2 min. Reactions were measured at 315 nm against a reagent blank.

High pressure freezing-freeze substitution and transmission electron microscopy

Gametophytes of P. patens GD06 and PpCESAKOs were high pressure-frozen using a Leica EMPACT2 high pressure freezer (Leica Microsystems, Inc.) followed by freeze-substitution in 0.1% uranyl acetate in acetone for 48 h at -90°C before the temperature was ramped up slowly to -50°C (Wilson and Bacic 2012). The samples were rinsed with acetone twice at -50°C before the acetone was replaced with ethanol.
and the samples were subsequently infiltrated with LR White resin (ProSciTech Pty. Ltd., Thuringowa Central QLD Australia) in a series of ethanol/resin dilutions. The samples were rinsed three times in 100% resin before polymerization with UV light at -20°C for 48 h. Thin sections (70 nm) were cut using a Leica Ultracut R (Leica Microsystems, Inc.) and post-stained with uranyl acetate and lead citrate (Wilson and Bacic 2012). Images were taken using a Tecnai G2 Spirit transmission electron microscope (FEI, Hillsboro, OR USA). Cell wall thickness was measured using ImageJ, Fiji version (Schindelin et al. 2012).

Ultrathin sections (70 nm) were also cut from blocks prepared for affinity cytochemistry (see above), mounted on Formvar coated copper grids, and stained with uranyl acetate and lead citrate (Wilson and Bacic 2012). Sections were imaged using a FEI/Phillips CM-200 transmission electron microscope (FEI).

**Sum Frequency Generation spectroscopy**

Leaves of wild type GD06, 8KO-5B, and 3/8KO-86 lines were mounted abaxial side down in water on glass slides and allowed to air-dry overnight. SFG spectra were collected 5 μm intervals along a 200 μm line scan perpendicular to the midrib at its thickest point using an SFG microscope system described previously (Lee et al. 2016). The SFG spectra were collected with the following polarization combination: SFG signal = s-, 800 nm = s-, and broadband mid-IR = p-polarized with the laser incidence plane and the laser incidence plane aligned along the axis of midrib.

**Reverse transcription quantitative PCR**

RNA was extracted from gametophores from two independent wild type and three independent lines each of ppcesa3KO and ppcesa8KO as described previously (Tran and Roberts 2016). cDNA samples were tested in duplicate as described previously using primer pairs for amplification of *PpCESA3* and *PpCESA8*. The primers have been previously tested for specificity and efficiency (Tran and Roberts 2016). Primers for actin and v-Type H⁺translocating pyrophosphatase reference genes were described previously (Le Bail et al. 2013). Target/average reference cross point ratios were calculated for each sample and standard errors were calculated for independent genetic lines.

**Statistical analysis**

For statistical analysis, one-way Analysis of Variance (ANOVA) with post-hoc Tukey Honest Significant Difference (HSD) test was performed at astatsa.com/OneWay_Anova_with_TukeyHSD/.

Figure legends

Figure 1: Phenotypes of *ppcesa3/8KO*, *ppcesa3KO* and *ppcesa8KO* compared to wild type *Physcomitrella patens*.  
(A-D) Colony morphology is similar in wild type, *ppcesa3KOs* and *ppcesa8KOs*; horizontal growth is typical of gametophores produced by *ppcesa3/8KO* (arrowheads). (E-H) Polarized light microscopy of leaves shows that the midribs of wild type and *ppcesa3KO* are highly birefringent. The midribs of *ppcesa3/8KO* leaves have low birefringence and *ppcesa8KO* leaves have moderate birefringence. (I-L) Fluorescence microscopy of leaves stained with S4B shows strong fluorescence in the midribs of wild type and *ppcesa3KO*, low fluorescence in the midribs of *ppcesa3/8KO* leaves and intermediate fluorescence in the midribs of *ppcesa8KO* leaves. (M-P) Differential interference contrast microscopy of sections through the midribs of maturing leaves (L=lamina cell, *=bundle sheath cell). In wild type and *ppcesa3KO*, the walls of bundle sheath cells and the stelar cells they surround show enhanced contrast due to higher refractive index. (Q-T) Fluorescence microscopy of the same sections shown in M-P labeled with CBM3a. The bundle sheath and stelar cells of wild type and *ppcesa3KO* leaves are strongly labeled, whereas labeling is weak in *ppcesa3/8KO* and intermediate in *ppcesa8KO* leaves.

Figure 2: Quantitative analysis of S4B fluorescence intensity in leaf midribs of *P. patens* wild type, *ppcesaKO*, and rescue lines. (A) Fluorescence was significantly weaker in *ppcesa3/8KOs* compared to wild type (WT). *ppcesa3KOs* were not significantly different from wild type, whereas *ppcesa8KOs* were intermediate between the wild type and *ppcesa3/8KOs* and significantly different from both. For each mutant genotype, three independent genetic lines were sampled in triplicate. Two independent wild type lines (GD06 and GD11) were sampled in triplicate. Bars indicate the standard error of the mean for three mutant (n=3) or two wild type (n=2) lines. Genotypes with different letters are significantly different. (B) Lines derived from transformation of *ppcesa3/8KO-86lox* with *proCESA8::CESA8* (8R) had significantly higher fluorescence compared to the parent double KO line and *ppcesa8KO*, but significantly less than WT. (C) Lines derived from transformation of *ppcesa3/8-86lox* with *proCESA3::CESA3* (3R) had significantly higher fluorescence compared to the parent double KO line (except 3R29) and were not significantly different from either *ppcesa8KO* lines (3R29 and 3R52) or WT (3R45). For B and C, three independent explants were sampled for each genetic line. Bars indicate the standard error of the mean for three explants from the same line (n=3 or n=2 (WT, 3/8KO, 8KO in C)).

Figure 3: Polarized light microscopy with first order retardation plate. Double pointed arrow indicates the vibration direction of the major axis. (A-C) Midrib of a mature wild type leaf oriented parallel, perpendicular, and at 45° to the major axis of the retardation plate. Bundle sheath cells (*) flank the
central midrib. (D) Midrib of a developing wild type leaf oriented parallel to the major axis of the retardation plate showing change in microfibril orientations through the basal (b), medial (m), and apical (a) regions of the midrib. (E-G) Midrib of a mature ppcesa3/8KO leaf oriented parallel, perpendicular, and at 45° to the major axis of the retardation plate. (H) Midrib of a developing ppcesa3/8KO leaf oriented parallel to the major axis of the retardation plate showing no change in microfibril orientation through the basal, medial, and apical regions of the leaf. Bar in A is also for B-C and E-G and bar in D is also for H.

Figure 4: Transmission electron microscopy images of leaf midribs of *P. patens* showing adjacent cells with primary cell walls (PW) and secondary cell walls (SW) in (A) wild type, and (B-D) mutant leaves.

Figure 5: Sum Frequency Generation (SFG) spectroscopy of *P. patens* leaves. (A) Full SFG spectra collected from leaf midribs (each is the average of nine spectra, from three different positions on each of three different leaves). A strong peak in the C-H stretch region (2944 cm⁻¹) is present in spectra from wild type (WT), greatly diminished in spectra from ppcesa8KO (8KO), and absent in spectra from ppcesa3/8KO (3/8KO). (B) *P. patens* wild type, ppcesa8KO, and ppcesa3/8KO leaves with SFG scan trajectories traversing the midribs. Step size was 5 μm/step. SFG spectra were collected from 2850 to 3150 cm⁻¹, covering the entire CH region. (C) 2D projection image of SFG spectra collected across the midribs of each leaf shown in B. Each column in each image is an entire spectrum collected from one point plotted against displacement along the scan trajectory. Colors indicate SFG intensity as shown in the legend.

Figure 6: RT-qPCR analysis of *PpCESA3* and *PpCESA8* expression in wild type, ppcesa3KO and ppcesa8KOs. Target/average reference cross point ratios (using actin and v-Type H⁺translocating pyrophosphatase reference genes) were determined for three independent lines of each mutant (3KO-5, -35, -126; 8KO-5B, -4C, -10C; and 3/8KO-43, -57, -86) and two independent wild type lines (GD06 and GD11) with two technical replicates each. Bars indicate the standard error of the mean for the three mutant (n=3) or two wild type (n=2) lines.

Figure 7: Quantitative analysis of S4B fluorescence intensity in leaf midribs. (A,B) Wild type (WT), ppcesa3/8KO-86lox, and ppcesa3/8KO-86lox transformed with *proCESA8::CESA* expression vectors. For each rescue genotype, three independent genetic lines were sampled in triplicate and measured with 6 samples of wild type (GD06) and 8 samples of ppcesa3/8KO-86lox. (A) For lines derived from transformation of ppcesa3/8KO-86lox with *proCESA8::CESA3* (8pro:3R), *proCESA8::CESA7* (pro8:7R), and *proCESA8::CESA10* (pro8:10R) genotypes, the three independent lines did not differ significantly and were combined. *proCESA8::CESA7* and *proCESA8::CESA10* lines did not differ significantly from
the parent double KO line ($p > 0.05$), whereas $\text{proCESA8::CESA3}$ lines had significantly higher fluorescence compared to the parent double KO line, but significantly less than WT ($p < 0.05$). Bars indicate the standard error of the mean for three independent lines. Genotypes with different letters are significantly different. (B) For lines derived from transformation of $\text{ppcesa3/8KO-86lox}$ with $\text{proCESA8::CESA5}$ (pro8:5R) and $\text{proCESA8::CESA4}$ (pro8:4R), the three independent lines were significantly different and were analyzed separately. $\text{proCESA8::CESA5}$ (5R) lines were not significantly different from the wild type ($p > 0.05$), except for 5R7, which was not significantly different from $\text{ppcesa3/8KO-86lox}$ ($p > 0.05$). $\text{proCESA8::CESA5}$ lines did not differ significantly from $\text{ppcesa3/8KO-86lox}$ ($p > 0.05$). Bars indicate the standard error of the mean for three gametophores from the same line (n=3). Lines with different letters are significantly different ($p < 0.05$). (C) Mid rib fluorescence was slightly, but significantly reduced in $\text{cesa4/10KO}$ compared to wild type ($p = 0.037$). Reduction in midrib fluorescence in $\text{cesa6/7KO}$ was substantial and highly significant ($p = 0.0011$). Bars indicate the standard error of the mean for three independent mutant lines or 3 replicates of wild type (n=3).

In wild type and *ppcesa3KO*, the walls of bundle sheath cells and the stericid cells they surround show enhanced contrast due to higher refractive index. (Q-T) Fluorescence microscopy of the same sections shown in M-P labeled with CBM3a. The bundle sheath and stericid cells of wild type and *ppcesa3KO* leaves are strongly labeled, whereas labeling is weak in *ppcesa3/8KO* and intermediate in *ppcesa8KO* leaves.
Figure 2: Quantitative analysis of S4B fluorescence intensity in leaf midribs of *P. patens* wild type, *ppcesa*KO, and rescue lines. (A) Fluorescence was significantly weaker in *ppcesa*3/8KO lines compared to wild type (WT). *ppcesa*3KO lines were not significantly different from wild type, whereas *ppcesa*8KO lines were intermediate between the wild type and *ppcesa*3/8KO lines and significantly different from both. For each mutant genotype, three independent genetic lines were sampled in triplicate. Two independent wild type lines (GD06 and GD11) were sampled in triplicate. Bars indicate the standard error of the mean for three mutant lines or two wild type lines. Genotypes with different letters are significantly different. (B) Lines derived from transformation of *ppcesa*3/8KO-86lox with *proCESA8::CESA8* (8R) had significantly higher fluorescence compared to the parent double KO line and *ppcesa*8KO, but significantly less than WT. (C) Lines derived from transformation of *ppcesa*3/8-86lox with *proCESA3::CESA3* (3R) had significantly higher fluorescence compared to the parent double KO line (except 3R29) and were not significantly different from either WT or the 3R45 line. Bars indicate the standard error of the mean for three explants from the same line (n=3 or n=2 (WT, 3/8KO, 8KO in C)).
Figure 3: Polarized light microscopy with red I retardation plate. Double pointed arrow indicates the vibration direction of the major axis. (A-C) Midrib of a mature wild type leaf oriented parallel, perpendicular, and at 45° to the major axis of the retardation plate. Bundle sheath cells (*) flank the central midrib. (D) Midrib of a developing wild type leaf oriented parallel to the major axis of the retardation plate showing change in microfibril orientations through the basal (b), medial (m), and apical (a) regions of the midrib. (E-G) Midrib of a mature ppcesa3/8KO leaf oriented parallel, perpendicular, and at 45° to the major axis of the retardation plate. (H) Midrib of a developing ppcesa3/8KO leaf oriented parallel to the major axis of the retardation plate showing no change in microfibril orientation through the basal, medial, and apical regions of the leaf. Bar in A is also for B-C and E-G and bar in D is also for H.
Figure 4: Transmission electron microscopy images of leaf midribs of *P. patens* showing adjacent cells with primary cell walls (PW) and secondary cell walls (SW) in (A) wild type, and (B-D) mutant leaves.
Figure 5: Sum Frequency Generation (SFG) spectroscopy of *P. patens* leaves. (A) Full SFG spectra collected from leaf midribs (each is the average of nine spectra, from three different positions on each of three different leaves). A strong peak in the C-H stretch region (2944 cm\(^{-1}\)) is present in spectra from wild type (WT), greatly diminished in spectra from *ppcesa8*KO (8KO), and absent in spectra from *ppcesa3/8*KO (3/8KO). (B) *P. patens* wild type, *ppcesa8*KO, and *ppcesa3/8*KO leaves with SFG scan trajectories traversing the midribs. Step size was 5 μm/step. SFG spectra were collected from 2850 to 3150 cm\(^{-1}\), covering the entire CH region. (C) 2D projection image of SFG spectra collected across the midribs of each leaf shown in B. Each column in each image is an entire spectrum collected from one pixel plotted against the corresponding displacement along the trajectory. Colors indicate SFG intensity as shown in the legend.
Figure 6: RT-qPCR analysis of *PpCESA3* and *PpCESA8* expression in wild type, *ppcesa3* KOs and *ppcesa8* KOs. Target/average reference cross point ratios (using actin and v-Type H^+^-translocating pyrophosphatase reference genes) were determined for three independent lines of each mutant (3KO-5, -35, -126; 8KO-5B, -4C, -10C; and 3/8KO-43, -57, -86) and two independent wild type lines (GD06 and GD11) with two technical replicates each. Bars indicate the standard error of the mean for the three mutant (n=3) or two wild type (n=2) lines.
Figure 7: Quantitative analysis of S4B fluorescence intensity in leaf midribs. (A,B) Wild type (WT), *ppcesa3/8KO-86lox*, and *ppcesa3/8KO-86lox* transformed with *proCESA8::CESA* expression vectors. For each rescue genotype, three independent genetic lines were sampled in triplicate and measured with 6 samples of wild type (GD06) and 8 samples of *ppcesa3/8KO-86lox*. (A) For lines derived from transformation of *ppcesa3/8KO-86lox* with *proCESA8::CESA3* (*8pro:3R*), *proCESA8::CESA7* (*pro8:7R*), and *proCESA8::CESA10* (*pro8:10R*) genotypes, the three independent lines did not differ significantly and were combined. *proCESA8::CESA7* and *proCESA8::CESA10* lines did not differ significantly from the parent double KO lines (*p* > 0.05), whereas *proCESA8::CESA3* lines had significantly higher fluorescence compared to the parent double KO line, but significantly less than WT (*p* < 0.05). Bars indicate the standard error of the mean for three independent lines. Genotypes with different letters are significantly different. (B) For lines derived from transformation of *ppcesa3/8KO-86lox* with *proCESA8::CESA5* (*pro8:5R*) and *proCESA8::CESA4* (*pro8:4R*), the three independent lines were significantly different and were analyzed separately. *proCESA8::CESA5* (*5R*) lines were not significantly different from the wild type (*p* > 0.05), except for 5R7, which was not significantly different from *ppcesa3/8KO-86lox* (*p* > 0.05). *proCESA8::CESA5* lines did not differ significantly from *ppcesa3/8KO-86lox* (*p* > 0.05). Bars indicate the standard error of the mean for three gametophores from the same line (n=3). Lines with different letters are significantly different (*p* < 0.05). (C) Mid rib fluorescence was slightly, but significantly reduced in *cesa4/10KO* compared to wild type (*p* = 0.037). Reduction in midrib fluorescence in *cesa6/7KO* was substantial and highly significant (*p* = 0.0011). Bars indicate the standard error of the mean for three independent mutant lines or 3 replicates of wild type (n=3).
