7 Abstract

8 There is widespread contamination by per- and polyfluoroalkyl substances (PFAS) across the 9 globe, with adverse effects on human and environmental health. For human exposure, drinking 10 water and dietary exposure have been recognized as important PFAS exposure pathway for the 11 general population. Several documented cases of dairy milk contamination by PFAS have 12 raised concerns over this exposure pathway in general. A sensitive method for determination of 13 27 PFAS in milk was hence modified and applied on raw and processed milk samples from 14 thirteen farms across the United States (U.S.). A combination of acid and basic extraction 15 method and ENVI-Carb cleanup achieved recoveries of targeted PFAS between 70-141%. The 16 method detection limits (MDL) ranged from 0.8-22 ng/L (for 26 PFAS) and 144 ng/L for 17 perfluorobutanoic acid (PFBA). The uniqueness of this method is considered in the targeted 18 screening of a broad range of legacy PFAS, as well as perfluorinated sulfonamide species and 19 fluorotelomer sulfonates. No legacy PFAS were detected in 13 milk samples from regions of 20 concern given local use of biosolids or proximity to fire training areas. Overall, then, the uptake 21 of perfluoroalkyl acids (PFAA) from dairy milk in the U.S. is considered low.

27 Introduction

28	Per- and polyfluoroalkyl substances (PFAS) comprise a broad group of anthropogenic
29	chemicals that are widely used in industrial and commercial applications [1]. These chemicals
30	display unique qualities such as lower micellization concentrations, ability to lower surface
31	tension of aqueous phases, hydrophobicity, and are oleophobic [2]. A variety of industries and
32	manufacturers have exploited these physicochemical properties to produce water repellent and
33	stain resistant coatings on textiles, oil-resistant food contact materials, and efficient aqueous
34	film forming foams (AFFF) [3]. As a result of their extensive use and chemical stability, PFAS
35	are ubiquitous in the environment and have been detected in wildlife and humans [4–6].

36 Extensive PFAS contamination in the environment has been predominantly linked to 37 applications of AFFF near airports, fire training areas, and military bases, as well as agricultural use of biosolids or sludge derived from wastewater treatment plants (WWTP) [5,7–9]. Prolonged 38 39 applications of AFFF and WWTP biosolids and sludge are attributed to elevated PFAS 40 concentrations in soil and groundwater, as well as surface and well water [10–15]. At numerous 41 sites impacted by AFFF and biosolids, the concentrations of perfluorooctane sulfonate (PFOS) 42 and perfluorooctanoic acid (PFOA) in drinking water dramatically exceeded the U.S. 43 Environmental Protection Agency (EPA) lifetime health advisory level of 70 ng/L for the 44 combined concentration of these two compounds [16-18].

45 Ingestion of such as contaminated drinking water is a significant human exposure pathway in 46 addition to PFAS ingested through diet [19,20]. In general, human dietary PFAS exposure 47 occurs by two main routes: i) direct exposure to PFAS present in unprocessed, raw products as a result of environmental contamination, and ii) indirect exposure to PFAS present in food 48 49 contact materials used in manufacturing, packaging, and preparation of processed food [21]. 50 Dietary PFAS exposure pathways and PFAS contribution vary for different populations [21]. For 51 instance, the European Food Safety Authority (EFSA) estimated that fish and seafood are 52 predominant pathways for chronic PFAS exposure in adults to PFOS (up to 86%). The EFSA 53 also projected that milk and dairy products are significant PFAS chronic exposure pathways to 54 vulnerable populations (e.g., toddlers) [20]. The PFAS contamination in milk and dairy products 55 could originate from processing and packaging of the final products, but most likely comes from 56 transfer of PFAS from feed to cows. This was previously demonstrated in both a dosing study 57 [22] and a descriptive model [23] in which dairy milk became a reservoir for PFAS. With a 58 continuous increase in annual milk production in the U.S. over the last decade [24], there is 59 plausible concern for increased risk of dietary exposure to PFAS to the general U.S population.

60 While a range of retail food studies including raw milk and other dairy products have been 61 conducted in both farm and local market products all over the world [21,25–30] a limited number 62 of reports exists for the U.S. domestic food supply. Previous studies have demonstrated that 63 livestock forage grown on biosolid-amended soils is an important driver of PFAS contamination 64 of the cattle [15,31]. Similarly, the use of organic fertilizers mixed with industrial wastes on 65 cropland has led to contamination of the cattle feedlots and subsequently to elevated PFAS 66 concentrations in animal by-products such as meat [22]. In multiple studies, the cattle exposed 67 to contaminated feed eliminate PFAS via lactational transfer [15,22,32]. Application of 68 contaminated biosolids has also been documented in farms across the U.S. for which PFAS 69 concentrations reached up to thousands of micrograms per kilogram of biosolids [15,31,33]. 70 Therefore, agricultural application of WWTP biosolids or industrial wastes or the proximity of 71 dairy farms to AFFF-impacted areas warrants concern for PFAA contamination in dairy 72 production.

Previous research on PFAS contamination of dairy cow milk has placed a greater emphasis on limited number of legacy perfluorinated alkyl acids (PFAA) with a focus on PFOA and PFOS [21,22,25,28–30,34,35]. Elevated contamination in milk was mostly attributed to the ability of PFAA to bind to β -lactoglobulin proteins in cow milk [26,36] however limited data exists on both milk concentrations and mechanism of binding/releasing of emerging PFAS associated with AFFF and WWTP biosolids applications such as polyfluorinated fluorotelomer sulfonates, perfluoroalkyl sulfonamidoacetic acids, and perfluoroalkyl sulfonamides [17,37].

Previously developed extraction methods for PFAS analysis in milk used a small volume of the
samples (1-5 mL) to minimize the lipid and protein content in the final extracts and prevent
potential matrix effect during the instrumental analysis [38–40]. Additionally, up-to-date
published milk extraction method targeted the legacy PFAA only, without including the novel
PFAA alternatives and precursors [21,22,25,26,28–30,35]. The aim of the present study was

therefore to i) modify solvent digestion and sample cleanup method for broader group of legacy,

86 emerging and precursor PFAS in raw dairy cow milk and ii) apply the extraction method on raw

87 dairy milk collected from U.S. dairy farms.

88 Materials and methods

89 Standards and reagents

90 The 8-point calibration curve (0.004 - 100 ng/mL), QA/QC instrumental performance check, and 91 surrogate standard were created using analytical PFAS standards purchased from Wellington 92 Laboratories (Ontario, Canada). Individual target PFAS and corresponding isotope labelled 93 analogues are listed in Table SI 1. Formic acid (99+%), ammonium hydroxide (28%-30%), and 94 liquid chromatography-mass spectrometry (LC-MS) grade methanol were purchased from 95 Fisher Scientific (Pittsburgh, PA, USA). Oasis WAX solid-phase extraction resin (30 µm) was 96 purchased from Waters (Milford, MA, USA) and ENVI-Carb cartridges (Supelco) were 97 purchased from Sigma-Aldrich.

98 Extraction Method Evaluation

99 To evaluate the efficiency of extraction methods, approximately 10 g of local market, whole-milk 100 was weighed into wide-mouth polypropylene jars (n = 9), spiked with representative native 101 PFAS standards (10 ng/sample) and placed overnight in a freezer at -15 °C before freeze drying 102 at -53 °C for ~60 hours in a LABCONCO FreeZone 2.5L benchtop freeze dry system. Freeze 103 dried milk (~2 g) was transferred to 15mL Corning® Falcon centrifuge tubes and divided into 104 treatment groups (n = 3 per treatment) based on extraction solvent and clean-up procedure: i) 105 0.1% formic acid in methanol followed by clean-up with only ENVI-Carb cartridges, ii) 0.1% 106 formic acid in methanol extraction followed by clean-up with Oasis WAX resin loaded atop of 107 ENVI-Carb cartridges, and iii) 0.1% ammonium hydroxide in methanol followed by clean-up with 108 Oasis WAX powder loaded atop of ENVI-Carb cartridges. To create the paired WAX resin with

ENVI-Carb cartridge, approximately 500 mg of WAX resin suspended in LC-MS-grade methanol
was transferred onto the Envi-Carb cartridge (1 g) with a pre-cleaned disposable pipette.

111 To extract PFAS from the milk matrix, 6 mL of solvent was added to samples according to 112 respective treatment groups. All samples were then vortexed for ~30 s, placed in an ultrasonic 113 bath for 20 min, and centrifuged at 4000 rpm for 10 min. ENVI-Carb cartridges were fixed to a 114 CHROMABOND SPE manifold. All cartridges were pre-cleaned prior to sample loading with ~3 115 mL each of 0.1% formic acid in methanol, 0.1% ammonium hydroxide in methanol, and finally 116 neutral methanol. The organic layer was then transferred with a disposable transfer pipette and 117 loaded onto the cartridges. 15 mL Falcon centrifuge tubes were placed inside the manifold to 118 capture milk extracts. Samples were allowed to elute under gravity. The pellet formed during 119 centrifugation was rinsed with $\sim 2 \text{ mL}$ of neutral methanol and resuspended, vortexed $\sim 30 \text{ s}$. 120 placed in an ultrasonic bath for 20 min, and centrifuged at 4000 rpm for 10 min. The organic 121 layer was then transferred as detailed above onto the respective ENVI-Carb cartridge after the 122 first extract eluted. After gravity elution of the last fraction, a final wash of ~1-2 mL of neutral 123 methanol was used to rinse the inside of the cartridge. Vacuum pressure (<15 psi) was applied 124 to the manifold to remove residual solvent extract bound within the cartridges. Approximately 9-125 10 mL of extraction eluent was present after SPE clean-up procedures. This eluent was 126 evaporated at 36 °C to ~0.5 mL under a gentle stream of nitrogen gas and spiked with mass 127 labeled PFAS mix (2 ng/sample). 40 μ L of the concentrated extract was diluted with 60 μ L of 4 128 mM ammonium acetate in water prior to LC-MS analysis.

129 Sample collection and storage

Milk samples (n = 13) were collected from 13 individual cattle farms across The United States
(Table SI 2, Figure 1). These dairy cattle farms reported use of biosolid amendments on
cropland or were located within proximity to AFFF-impacted soils. Samples were shipped on ice
in original storage containers. All sample storage containers, extraction vessels, and transfer

pipettes were pre-cleaned with ACS-grade methanol, 3% ammonium hydroxide in LC-MS-grade
methanol, and LC-MS-grade methanol prior to use. Thawed milk samples were partitioned into
pre-cleaned 1 L HDPE bottles for storage at -15 °C. Locally purchased pasteurized whole milk
was used for determinations of dairy matrix interference with instrument detection. Samples
were analyzed within their shelf lives. A representative summary of sample collection locations
can be found in Table SI 2.

140

141 Figure 1: Map of milk samples location in selected states (Colorado, Maine,

Michigan, Pennsylvania, Texas and Wisconsin) in The United States

142

143 Sample preparation

144 Frozen milk samples were allowed to thaw at room temperature and well mixed before ~25 g of 145 thawed samples were weighed into pre-cleaned 50-mL polypropylene Corning® Falcon 146 centrifuge tubes. All samples, duplicates, matrix spikes and blanks were spiked with mass 147 labeled surrogate PFAS standard mixture (4 ng/sample). Additionally, a native PFAS solution (4 148 ng/sample) was added to matrix spike milk samples. Sample aliquots were frozen overnight at -149 15 °C, followed by -80 °C for five hours the next day, before freeze-drying in a LABCONCO® 150 FreeZone2.5 for 60 h at -54 °C. After freeze-drying, sample extraction was conducted using a 151 combined solvent digestion procedure.

152 Briefly, 12 mL of 0.1% formic acid in LC-MS-grade methanol was added to each freeze-dried 153 milk sample to denature proteins. Samples were then vortexed for ~30 s and placed in an ultra-154 sonic bath for 25 min at room temperature before centrifugation at 4000 rpm for 10 min. The 155 organic supernatant was then transferred to a 15 mL Corning® Falcon centrifuge tube and 156 concentrated down to ~1 mL under a gentle stream of nitrogen gas to allow room for additional 157 aliquots. Following the initial concentration step, 6 mL of LC-MS-grade methanol was added to 158 the original pellet formed in the first solvent digestion step. The same vortex, sonication, and 159 centrifugation steps were repeated. After centrifugation, the organic supernatant was transferred 160 and combined with the concentrated acidic digestion extract. Lastly, a final solvent digestion 161 was performed with 6 mL of 0.1% ammonium hydroxide in methanol following the same 162 procedures as outlined in the previous solvent digestions. A final sample concentration under a 163 gentle stream of nitrogen gas down to ~4 mL was performed. The final volume extracts were 164 stored overnight at -15 °C to promote precipitation of residual matrix within extracts. 165 The sample clean-up procedure was performed with ENVI-carb (1 g. Supelco) cartridges. 166 Cartridges were affixed to a CHROMABOND® SPE manifold and precleaned with 2 mL each of 167 0.1% formic acid in methanol, 0.1% ammonium hydroxide in methanol, and lastly LC-MS-grade 168 methanol. Prior to loading, samples were taken out of freezer storage, centrifuged to remove 169 residual matrix for 1 min at 4000 rpm. The supernatant was then transferred into ENVI-carb 170 cartridges and allowed to elute under gravity (~1 drop/sec) into fresh 15 mL Corning® Falcon 171 centrifuge tubes. A 1 mL wash with LC-MS-grade methanol was performed on the original 172 storage tube and centrifugation for 1 min at 4000 rpm conducted prior to loading this extract to

174 aliquot. Lastly, vacuum pressure (~10 psi) was applied to elute residual solvent extract bound

the cartridge. Additionally, cartridges were rinsed with a final 1 mL LC-MS-grade methanol

175 within the cartridge. Eluents were concentrated down to ~0.5 mL under a gentle stream of

176 nitrogen gas before preparation for HPLC-MS/MS analysis.

173

177 Instrumental LC-MS analysis

The LC-MS/MS analysis of targeted PFAS (Table SI 1) was performed using a liquid
chromatograph (Shimadzu Prominence UFLC) equipped with a Gemini C18 hybrid column (3
µm, 2.1 mm X 50 mm; Phenomenex) coupled to mass spectrometer (AB Sciex 4500 QTRAP)
operating in negative ion mode. To reduce background contamination in the system, a delay
column (Luna 5 µm C18(2) 100 Å, LC Column 30 x 2 mm) was installed to the LC system. For
analysis, 20 µL of prepared extract was injected on the analytical column and PFAS were
separate and determined (all analytical details are listed in SI, Table SI 3, 4 and 5 and in [41]).

185 **QA/QC**

186 The calculations of the PFAS concentration in samples and quality control samples was based 187 on the isotope dilution method of quantitation. To guarantee quality control, three process 188 blanks and two matrix spikes blanks were included within each batch of 14 samples. Blank 189 concentrations were <10% of the measured samples, and due to this low background 190 contamination level, sample concentrations were not blank corrected. The method detection 191 limits (MDL, ng/L) were determined considering the following criteria: in case no analyte signal 192 was detected in the process blanks, instrumental detection limits (IDL) were used as MDL and 193 an appropriate dilution factor was applied. IDL represents the concentration of analyte giving the 194 signal-to-noise ratio of 10 in presence of the matrix. In case the analytes were detected in 195 process blanks, MDL were calculated as average value plus 3 times the standard deviation (SD) 196 of the concentrations in all blanks. MDLs and recoveries for all targeted PFAS are listed in Table 197 1 (with details in SI). Additionally, recoveries of the surrogate mass labeled PFAS spiked into 198 the real samples, blanks and quality control samples were withing 60-140%.

199 **Results and discussion**

200 Extraction Method Evaluation

The extraction method (solid liquid extraction, SLE) evaluation incorporated nine retail milk
replicates for which two different extraction solvents and two different clean-up methods were
utilized. When extracting PFAS from milk, it is common to incorporate solvents or salts to
denature and precipitate proteins and other biochemical artifacts that may bind PFAS, such a β
-lactoglobulin [25,26,28]. For these reasons, a similar approach was applied, relying on either
0.1% formic acid (FA) in methanol (treatment 1 and 2) or 0.1% ammonium hydroxide (AH) in
methanol (treatment 3).

A summary of 22 native PFAS recoveries from extraction is provided in Figure 2. Average

209 recoveries for the C4-C10 PFCAs was generally over 60% between treatments (Fig. 2a).

Among the C4-C11 PFCAs, incorporation of ~500 mg WAX powder loaded atop of the ENVI-

211 Carb cartridge (1 g) did not result in significantly higher recoveries. Recoveries of the C12-C14

212 PFCAs were generally over 50% except for PFTeDA (treatment 2). Average recoveries of C4

and C6-C8 PFSAs (Fig. 2b) ranged from 48% to 51% with basic digestion (treatment 3)

214 extraction being most optimal for the recovery of the sulfonates. PFBS had the greatest

215 recovery of the PFSAs at 63%. Recovery of the sulfonamides (Fig. 2c): FBSA, FOSA, *n*-

216 MeFOSA, and *n*-EtFOSA ranged from 23% to 71% across experiments with recovery of FOSA

217 being the highest at 71% in Treatment 1. The recoveries for *n*-MeFOSA, and *n*-EtFOSA were

218 overall low, so these compounds were excluded from further evaluations. Recoveries for the

219 fluorotelomer sulfonates (Fig. 2d) ranged from 42% to 68%, with highest average recovery

across treatment groups residing with 6:2 FTS at 68%, and lowest average recovery with 4:2

FTS at 42%. Generally, the target PFAA and polyfluorinated precursors had recoveries of ~60%

on average. The WAX powder allowed for greater separation of C4-C12 PFCA, PFBS, PFHxS,

223 PFHpS, PFOS, and other perfluorinated species from the interfering matrix. However, the

224 recoveries for longer chain PFCA which are known for their bioaccumulative properties [42] 225 were higher on average for Treatment 3 which incorporated use of 0.1% ammonium hydroxide 226 in methanol. The recoveries of PFCA were generally higher in Treatment 3 when compared to 227 Treatment 1. A similar pattern can be seen with the PFSA and 6:2 FTS. Slight differences were 228 evident in the recovery for PFOS between Treatment 1 and Treatment 3 (Fig. 2b). These 229 patterns provided justification to utilize a stepwise solvent extraction which incorporates both 230 acidic and basic organic solvents to account for the broad spectrum of predominant PFAS found 231 in WWTP wastewater and biosolids, as well as AFFF [14,37,43–45]. Therefore, the combination 232 of the treatment 1 and 3 was applied on the real milk samples to achieve maximum recoveries 233 for all targeted group of PFAS.

242 Analysis of real milk samples

243 A total of thirteen raw and retail milk samples were collected from U.S. dairy farms that either 244 had confirmed use of biosolids on cropland or were within geographic proximity to military 245 installations with confirmed AFFF use. PFAS present in AFFF utilized at fire training areas and 246 military bases may persist in soils and groundwater leachate [17,46,47]. PFAS recalcitrance in 247 soils due to AFFF leachate irrigation or biosolid amendment application pose reasonable 248 concerns for agriculture [48]. Concentration of PFOA and PFOS in plants grown in biosolid 249 amended soils have previously been found up to 200 ng/g dw and 20 ng/g dw, respectively [49]. 250 PFOS concentrations in biosolids from previous studies found as little as 4.3 to 89 μ g/kg dw [50] 251 to as much as $3120 \mu g/kg$ in the U.S. [31], reaching elevated concentrations that have 252 ubiquitous concern for biosolid use in agriculture. Where WWTP biosolids have been spread on 253 cropland, PFOS concentrations have been quantified up to 483 µg/kg dw [33,51] took into 254 consideration WWTP biosolid amendments and the likely occurrence of biotransfer from crop to 255 organism by providing toxicokinetic evidence of PFOA uptake and elimination in beef cattle. 256 Following this, Kowalczyk et al. (2013) demonstrated elimination of PFAS from naturally 257 contaminated feed, in part, through lactational transfer [22]. Accumulation of PFAS in animal by-258 products therefore serves as a possible endpoint for exposure to humans who incorporate dairy 259 milk in their diet. Both the proximity of farms to AFFF-impacted soils and the presence of WWTP 260 biosolids on croplands raises concerns for bioaccumulation in food animals whose feed is 261 obtained from the cropland.

A targeted LC-MS analysis of 27 PFAS (Table SI 1) was conducted on the raw and retail milk samples for which a combined solvent extraction and ENVI-Carb clean-up was performed. The efficiency of the modified solvent digestion extraction and clean-up procedure is summarized in Table 1. The overall recoveries of the 27 PFAS were evaluated by using a real milk samples spiked with native PFAS solution (4ng per sample). The recoveries were calculated using the

267 isotope dilution method. Recoveries for the 27 targeted analytes ranged from $69 \pm 9\%$ to $141 \pm$ 268 5%. The average recovery amongst the PFAA (13 compounds) was 93%, similar to recoveries 269 for PFCA with CF₂ \leq 10 previously determined in other studies [21,26,28], which ranged from 70 270 to 120%. Only Lacina et al. [26] demonstrated similar performance for longer chain PFCA using 271 a multistep ion pair extraction and cleanup method. Within the group of PFAS (8 compounds) 272 the method achieved an average recovery of 113%, ranging from $90 \pm 6\%$ to $141 \pm 5\%$, the 273 lowest being PFECHS and PFNS as the highest, respectively. In above mentioned studies the 274 smaller range of PFSA (3 to 5) was dominantly analyzed with recoveries ranging from 70 to 104%. For the 4 sulfonamides and sulfonamide acids, the average recoveries were 97%. 275 276 Recovery for the only previously determined sulfonamide from this group (FOSA) was 107 ± 277 1 % which is comparable to previously published recoveries 98% [26]. Lastly, recoveries of the 278 fluorotelomer sulfonates (3 compounds) ranged from $98 \pm 3\%$ to $136 \pm 7\%$, with lowest recovery 279 of 6:2 FTS and highest recovery of 8:2 FTS, respectively.

284 We evaluated the method performance on the real samples and calculated the method 285 detection limits (MDLs) for the SLE-HPLC-MS/MS as described above. Generally, MDL ranged 286 from 0.8-22 ng/L for 26 PFAS and 144 ng/L for PFBA, which is known for a strong matrix 287 interference. Achieved MDL are far below the only established action level for PFAS (PFOS; 288 210 ng/L) in cow's milk developed by Maine Department of Agriculture, Conservation and 289 Forestry (DACF) the Maine Center for Disease Control and Prevention (MECDC) [52]. 290 The uniqueness of this method is considered in the targeted screening of a broad range of 291 legacy PFAS, as well as perfluorinated sulfonamide species and fluorotelomer sulfonates, for 292 which MDL <5.2 ng/L were achieved. To our knowledge, this is one of the first studies to screen 293 such a variety of legacy and emerging PFAS in the U.S. produced milk.

The stepwise solvent digestion method incorporating the use of acidic, and basic methanolic solvents for initial extraction of PFAS in cow milk is the first of its kind in the literature together with a condensed clean-up to a single ENVI-Carb cartridge to help remove milk sample matrix. This improved clean-up and extraction method achieved recoveries that were as good as or better for target PFAS in comparison to other dairy cow milk studies where MDLs varied between hundreds pg/L to tens ng/L for limited number of PFAA [21,22,25,26,28–30,35].

302 * NA – not analyzed in the particular study

303 The present study included milk samples that were collected from a variety of rural dairy farms 304 that sell to local markets and larger urban areas (Table SI 1, Figure 1). The only analyte 305 detected in this study was 6:2 FTS at concentration 6.6 ng/L, for which a lack of data is 306 available from previous studies regarding contamination in dairy cow milk (Table 2). To our 307 knowledge, the only other U.S.-based study (Table 2) similarly investigated biosolid-amended 308 croplands and concerns for accumulation of PFAS in dairy milk and quantified only PFOS (0.16 309 ng/L) above its MDL (0.13 ng/L) [21]. Both 6:2 FTS and PFOS can commonly be found in both 310 AFFF leachate and WWTP biosolids [10,44]. With PFAS concentrations in most milk samples 311 being below their MDLs, and a representative number of dairy farms and locations included in 312 this study, the data suggests that consumption of dairy milk is not a prominent source of dietary 313 PFAS exposure. Similarly, proximity to military zones with historical AFFF use does not seem to be a factor. However, as recent evidence suggests, the presence of biosolids containing PFAS
may lead to contamination in soils and plants on cropland [15]. Especially short chain PFAA
such as PFBA, PFPeA and PFBS are well known to be accumulated by agriculture plants
[54,55] but it is unknown as to whether the cattle on these farms frequently graze on cropland
associated with biosolid spreading or if these short chain PFAA which show different elimination
kinetics compare to the long chain PFAA due to smaller molecular size have been excreted via
urine [22].

321 Conclusion

322 The method presented in this study demonstrated enhanced capacity to quantitatively analyzed 323 a broad range of PFAS in dairy milk in sub ng/L using a combined solvent extraction and single 324 step clean-up procedure. Using this method, we screened raw and processed milk samples 325 from dairy cattle farms which reported use of biosolid amendments on cropland or were located 326 within proximity to AFFF-impacted soils. While levels of legacy PFAS formerly known to 327 accumulate in a variety of dairy products were below detection limits, the fluorotelomer sulfonate 328 (6:2 FTS) was detected in one sample. These findings might reflect shifts in the AFFF 329 compositions thus the further exploration of PFAS contamination of dairy products using non-330 targeted screening or total extractable fluorine approach might be essential.
