Abstract

Nucleotide excision repair (NER) is a major repair pathway that recognizes and corrects various lesions in cellular DNA. We hypothesize that damage recognition is an initial step in NER that senses conformational anomalies in the DNA caused by lesions. We prepared three DNA duplexes containing the carcinogen adduct N-(2'-deoxyguanosin-8-yl)-7-fluoro-2-acetylaminofluorene (FAAF) at G1, G2 or G3 of NarI sequence (5'-CCG1G2G3CC-3'). Our 19F-NMR/ICD results showed that FAAF at G1 and G3 prefer syn S- and W-conformers, whereas anti B-conformer was predominant for G2. We found that the repair of FAAF occurs in a conformation-specific manner, i.e. the highly S/W-conformeric G3 and -G1 duplexes incised more efficiently than the B-type G2 duplex (G3/C24G1 > G2). The melting and thermodynamic data indicate that the S- and W-conformers produce greater DNA distortion and thermodynamic destabilization. The N-deacetylated N-(2'-deoxyguanosin-8-yl)-7-fluoro-2-aminofluorene (FAF) adducts in the same NarI sequence are repaired 2- to 3-fold less than FAAF: however, the incision efficiency was in order of G2/G1 > G3, a reverse trend of the FAAF case. We have envisioned the so-called N-acetyl factor as it could raise conformational barriers of FAAF versus FAF. The present results provide valuable conformational insight into the sequence-dependent UvrABC incisions of the bulky aminofluorene DNA adducts.

Introduction

Adduct formation is an important aspect of DNA damage: if unrepaired, various mutations in DNA could occur (1–3). The presence of mutations on specific oncogenes or tumor suppressor genes may trigger cancer initiation. Human cells are armed with various effective repair pathways to safeguard genomic DNA from continuous assault by exogenous and endogenous sources (4). Nucleotide excision repair (NER) is a major repair pathway that is known for the removal of stretches of bases containing various lesions, including single-base damages, bulky adducts and cross-links, among others (5). Deficiencies in NER are closely associated with the development of several genetic diseases, such as xeroderma pigmentosum that increases the risk of skin cancer due to higher sensitivity to sunlight (6).

The NER pathway in Escherichia coli involves the UvrABC nuclease system and has been studied extensively for understanding DNA damage recognition and incision. E. coli NER is initiated following damage recognition by a dimeric UvrA protein. Next, UvrB protein reaches the damage site, forms a trimer and verifies the damage. Departure of UvrA from the resulting complex recruits UvrC and UvrD proteins, which cleave and remove the lesion-bearing patch of DNA. Finally, DNA polymerase I synthesizes and ligase I seals a new patch to complete the repair process (5,7).
Arylamines are an important class of environmental pollutants that are implicated in the etiology of human cancers, especially of the bladder and liver (1). 2-Acetylaminofluorene was originally developed as an agricultural insecticide, but was later banned due to its strong tumorigenic activity in rat livers (8). It has been used extensively as a model for studying chemical carcinogenesis. In vivo, metabolic activation of AAF produces a highly electrophilic nitrenium ion, which subsequently interacts with DNA to produce two major C8-substituted dG adducts: AAF and AF (Figure 1a) (8,9). In vitro, N-acetylated AAF blocks the activity of high-fidelity polymerases and requires bypass polymerases for a translesion synthesis (TLS), whereas AF only slows down replication (10). In general, the bulky AAF exhibits greater susceptibility to NER than AF (11), which is known to exist in a sequence-dependent equilibrium between anti B-conformer and syn S-conformer (Figure 1c) (10,12–14). We recently reported that AAF adducts also adopt a sequence-dependent S/B/W-conformational equilibrium (Figure 1d) (15).

Local sequence context plays an important role in the repair of arylamine–DNA adducts (16). Fuchs et al. constructed DNA sequences modified with AAF at each of three guanines of the most frequently studied mutational hotspot known as NarI sequence (5’-...CG1G2CG3CC...-3’) and tested their substrate repairability in the E. coli UvrABC and human exonuclease systems. In E. coli, the three AAFs were repaired in a sequence-dependent manner, with relative repair efficiencies of G1:G2:G3 in a ratio of 100:18:66 (17,18). However, different repair efficiencies were observed for the same lesions by the human exonuclease, 38:100:68 for G1, G2 and G3, respectively (18). AAF at G3 of NarI sequence induces ~100-fold greater frequency of –2 frameshift (~2 deletion) mutations, even though the three guanines exhibit similar chemical reactivities (19). We have shown that the FAF-modified NarI -2 deletion duplex in the 5’–CG1G2CG3*CC–3’ context adopts a single looped-out bulge structure, whereas the 5’–CG1G2CG3*CT–3’ context results in a local conformational heterogeneity (20). These results support the importance of the 3’-next flanking nucleotide to the lesion in modulation of mutation efficiency. The studies verified that the conformational stability of a slipped mutagenic intermediate is a critical determinant for the hotness (up to 30- to 50-fold) of G3 in NarI sequence for –2 frameshift mutation (20–22). Mekhovich et al. (23) found a greater incision rate in E. coli systems when AAF was located at G3 of the NarI sequence (5’–CG1G2CG3*CC–3’) than in a non-NarI sequence (5’–GATG*ATA–3’). Zou et al. (24) have reported that the UvrABC incision efficiency is 70% more in the TG*T than in the CG*C sequence context when adducted with either AF- or AAF lesions.

The NER pathway is characterized by its unique ability to excise a wide array of structurally diverse DNA lesions. The structure of individual adducts per se is not as important as lesion-induced local distortions and destabilizations to trigger a NER response. Examples include disruption of Watson–Crick hydrogen bonding, DNA bending, thermodynamic destabilization, local conformational flexibility and flipped-out bases in the unmodified complementary strand (25,26). However, mechanisms of sequence dependence that control NER efficiencies remained elusive.

![Figure 1](image_url)

**Figure 1.** (a) Chemical structures of AAF, FAAF, AF and FAF adducts; (b) sequences of fully paired 16-mer and 12-mer NarI duplexes used in the present study; major groove views of the central trimer segments of (c) the B/S and (d) B/S/W-conformer equilibrium of FAF and FAAF-modified duplexes. The modified dG and the complementary dC are shown in red and green sticks, respectively, and the aminofluorene moiety is highlighted with shiny gray CPK and the N-acetyl with pink CPK. In the B-type conformer, anti-[FAAF/FAF]dG maintains Watson–Crick hydrogen bonds, thereby placing the carcinogen moiety in the major groove. The carcinogens in the S- and W-conformers stack into the helix or wedged into the minor groove, respectively, with the modified dG in the syn conformation.
It could be that the observed local sequence effects described in the previous paragraph for AF and AAF are due to differences in the extent of distortions, which in turn depends on the conformation adopted in a particular sequence context.

In the present work, we investigated the role of conformational heterogeneity in the structure-repair relationships of AF and AAF. These two adducts are structurally similar, but differ in the absence and presence, respectively, of an N-acetyl group on the central nitrogen. We prepared oligonucleotides that were site-specifically modified by the fluorine model FAF and FAAF at three different guanines (G₁, G₂ and G₃) of the NarI recognition sequences (Figure 1a and b). We conducted spectroscopic and melting experiments for conformational and thermodynamic analyses. Moreover, we performed NER studies of these adducts using the E. coli UvrABC system. The results present strong structural and thermodynamic evidences for the differential NER efficiencies exhibited by AF and AAF at different guanine residues of the NarI sequence.

**MATERIALS AND METHODS**

**Caution**

2-Aminofluorene derivatives are mutagens and suspected human carcinogens and therefore must be handled with caution.

Crude oligodeoxynucleotides (ODN, 10 μmol scale) in desalted form were purchased from Eurofins MWG operon (Huntsville, AL, USA). All HPLC solvents were purchased from Fisher Inc. (Pittsburgh, PA, USA).

**Preparation and characterization of FAF- and FAAF-modified ODNs**

We previously reported the preparation of 12-mer NarI ODNs (5'-CTCG₁G₂CG₃CCATC-3') in which each of the three guanines were site-specifically modified by FAF (20). We have also demonstrated that the incorporation of fluorine atom at the longest axis position 7 does not affect the overall conformational and thermal/thermodynamic profiles of AF- or AAF-modified duplexes (14,20). The three FAF-modified NarI sequences were each annealed with a complementary 12-mer sequence (5'-GATGCGGC CGAG-3') to form fully paired NarI-G₁-FAF, NarI-G₂-FAF and NarI-G₃-FAF duplexes, respectively. These duplexes were thoroughly characterized by ¹⁹F-NMR, CD and UV melting experiments (20).

FAAF-modified 16-mer ODN were prepared using the general procedures described previously (15,27). Briefly, approximately 0.5–1 mg of N-acetoxy-N-2-(acetylamino)-7-fluorofluorene dissolved in absolute ethanol was added drop wise to a sodium citrate buffer (pH 6.0) containing 200–250 ODs of unmodified ODN (5'-CTCTCG₁G₂CG₃CCATCAC-3') and placed in a shaker for 5 min at 37°C. Figure 2a shows a typical reversed-phase HPLC chromatogram derived from the resulting mixture. The FAAF modified oligomers appearing between 28 and 85 min were separated and purified up to >97% purity by repeated injections. The HPLC system consisted of a Hitachi EZChrom Elite HPLC unit with an L2450 diode array detector and a Phenomenex Luna C18 column (150 × 10 mm, 5.0 μm). We employed a gradient system involving 3–15% acetonitrile for 40 min followed by 15–20% and 20–35% acetonitrile for 20 and 40 min, respectively, in pH 7.0 ammonium acetate buffer (100 mM) with a flow rate of 2.0 ml/min.

The three FAAF-modified 16-mer sequences were each annealed with the complementary sequence (5'-G'TGATG GCGCCGAGAG-3') to form fully paired NarI-G₁–FAAF, NarI-G₂–FAAF and NarI-G₃–FAAF duplexes for UV melting, DSC, CD and dynamic ¹⁹F-NMR experiments.

**LC/MS characterization of FAAF-modified ODNs**

Electrospray ionization and quadrupole time-of-flight mass spectrometry was utilized to verify the molecular weights and the position of FAAF attachment of the

---

**Figure 2.** (a) Chromatogram of a reaction mixture between 16-mer NarI sequence (5'-CTCTCG₁G₂CG₃CCATCAC-3') and an activated FAAF (N-acetoxy-N-2-(acetylamino)-7-fluorofluorene). The mono- (G₁, G₂, G₃), di- and tri-FAAF adducts eluted in the 28–35, 42–60 and 84 min were purified by reversed-phase HPLC (see ‘Materials and Methods’ section for gradient condition); (b) online photodiode array UV/Vis spectra of mono-, di- and tri-FAAF adducts.
three oligomers. The 16-mer ODNs were sequenced using 3′–5′ or 5′–3′ exonucleases as described previously for the analysis of modified 12-mers (28). Normally, 1 μg of a particular ODN was combined with 0.01 units of an exonuclease in a 1 mM solution of MgCl₂ and incubated for several hours. The digests were separated using a Phenomenex Aqua C18, 1.0 × 50 mm column (5 μm; 120 Å). Solvent A was 5 mM in both ammonium acetate and dimethylbutyl amine. Acetic acid was added to solvent A to adjust the pH to 7.0. Solvent B was 0.1% formic acid in acetonitrile. The flow rate was 100 μl/min and total run time was 20 min. All LC/MS spectra were acquired using a Waters SYNAPT quadrupole time-of-flight mass spectrometer (Milford, MA, USA) operated in the negative ion and V-modes. The measured molecular masses of all three isomeric ODNs were within 0.1 Da of their theoretical monoisoisotopic mass (5016.9 Da).

UV melting

UV melting data were obtained using a Cary100 Bio UV/VIS spectrophotometer equipped with a 6 × 6 multi-cell block and 1.0 cm path length. Sample cell temperatures were controlled by an in-built Peltier temperature controller. Oligonucleotide duplexes with a concentration range of 0.4–6.4 μM were prepared in solutions containing 0.2 M NaCl, 10 mM sodium phosphate and 0.2 mM EDTA at pH 7.0. Thermomelting curves were constructed by varying temperature of the sample cell (1°C/min) and monitoring absorbance at 260 nm. A typical melting experiment consisted of forward/reverse scans and was repeated five times. Thermodynamic parameters were calculated using the program MELTWIN version 3.5 as described previously (12).

Circular dichroism (CD)

Circular dichroism (CD) measurements were conducted on a Jasco J-810 spectropolarimeter equipped with a Peltier temperature controller. Typically, 2 ODs of each strand were annealed with an equimolar amount of a complementary sequence. The samples were dissolved in 400 μl of a neutral buffer (0.2 M NaCl, 10 mM sodium phosphate, 0.2 mM EDTA) and placed in a 1.0 mm path length cell. The samples were heated at 85°C for 5 min and then cooled to 15°C, over a 10 min period to ensure complete duplex formation. Spectra were acquired every 0.2 nm with a 2 s response time from 200 to 400 nm at a rate of 50 nm/min, were the averages of 10 accumulations and were smoothed using 17-point adaptive smoothing algorithms provided by Jasco.

Dynamic 19F-NMR

Approximately 20 ODs of a pure FAAF-modified 16-mer ODN was annealed with an equimolar amount of a complementary sequence to produce a fully paired duplex (Figure 1b). The samples were then dissolved in 300 μl of typical pH 7.0 NMR buffer containing 10% D₂O/90% H₂O, 100 mM NaCl, 10 mM sodium phosphate and 100 μM EDTA, and then cooled to 15°C. Spectra were acquired every 0.2 nm with a 2 s response time from 200 to 400 nm at a rate of 50 nm/min, were the averages of 10 accumulations and were smoothed using 17-point adaptive smoothing algorithms provided by Jasco.

Substrate construction and UvrABC protein purification

DNA substrates of 55 bp containing a FAAF adduct at each of three guanine residues were constructed as previously described (11,32). Briefly, an FAAF-modified 16-mer ODN (5′-CTCTCGGCGCCATCAC-3′) was ligated with flanking 20-mer ODN (5′-GACTACGTTACTGTACGGGCT-3′) and 19-mer ODN (5′-GCAATCCGCCAGTCTGC-3′) ODN at the 5′- and 3′-end, respectively (Supplementary Figure S1). The 20-mer was
S’-terminally labeled with $^{32}$P. The ligation product was purified by urea-PAGE under denaturing conditions. Following the purification, the substrate was annealed to the corresponding complementary strand, and then purified on an 8% native polyacrylamide gel. Similar procedures were employed to construct FAAF-modified DNA substrates using 12-mer NarI sequence (5'-CTCTC,G2,CG3,CCATC-3'), which we prepared previously for $^{19}$F-NMR/UV/ICD studies (20).

UvrA, UvrB and UvrC proteins were over expressed in E. coli and then purified as previously described (33). The estimated purity of the three proteins was >95%. A Bio-Rad Protein Assay was used to determine the protein concentration with BSA as the standard based on the manufacturer-recommended procedures.

**Nucleotide excision assay and quantification of incision products**

The S’-terminally labeled DNA substrates were incised by UvrABC as previously described (11,32). Briefly, the DNA substrates (2 nM) were incubated in the UvrABC reaction buffer (50 mM Tris–HCl, pH 7.5, 50 mM KCl, 10 mM MgCl$_2$, 5 mM DTT) at 37°C in the presence of UvrABC (UvrA, 10 nM; UvrB, 250 nM; and UvrC, 100 nM). The Uvr proteins were diluted and premixed in Uvr storage buffer before addition to the reaction. Aliquots were collected at 0, 5, 10, 15 and 20 min into the reaction. The reaction was terminated by heating at 95°C for 5 min. The products were denatured by addition of formamide loading buffer and heating to 95°C for 5 min, followed by quick chilling on ice. The incision products were then analyzed by electrophoresis on a 12% polyacrylamide sequencing gel under denaturing conditions with TBE buffer.

To quantify the incision products, radioactivity was measured using a Fuji FLA-5000 Image Scanner with MultiGauge V3.0 software. The DNA incised (fmol) by UvrABC was calculated based on the total molar amount of DNA used in each reaction and the ratio of the radioactivity of incision products to total radioactivity of DNA. At least three independent experiments were performed for determination of the rates of incision.

**RESULTS**

**Model sequences**

We previously used FAF-modified 12-mer duplexes (5'-CTCTC,G2,CG3,*CNATC-3', N = C or T) to probe the impact of flanking and 3'-next flanking sequences on NarI-induced frameshift mutagenesis (20). Initially, we tried to use the same 12-mer NarI sequence for FAAF-modification for sake of comparison and consistency; however, the sequence was unsuitable for FAAF. Although FAAF adduction on the 12-mer NarI sequence was facile, a resulting reaction mixture was difficult to purify on the reverse phase HPLC system (see asterisked peaks in Supplementary Figure S2). Moreover, ligation efficiencies of the FAAF-modified 12-mers, particularly on the G$_1$- and G$_2$-positions, were very low. Accordingly, the length of DNA was increased to 16 (5'-CTCTC,G2,CG3,CCATC-3', Figure 1b) by adding two nucleotides (underlined) on either side of the 12-mer. The resulting FAAF-modified 16-mer ODNs were separated well on a reverse-phase HPLC and exhibited excellent ligation efficiencies (see below).

Figure 2a shows an HPLC profile of a work-up mixture after 20 min of reaction. Unreacted control ODN appeared at 21 min, followed by seven FAAF-modified ODNs in three retention time zones: Peaks 1–3 at 28–35 min, Peaks 4–6 at 42–60 min and Peak 7 at 84 min.

**ESI-QTOF-MS characterization**

The molecular weights of all three FAAF-modified 16-mer ODNs in the present study is similar to that of the AAF-modified 15-mer NarI sequence (5'CTCTC,G2,CG3,CCCTC-3') reported by Tan et al. (34). These results indicate that AAF and FAAF are chromatographically comparable, irrespective of sequence length, as long as the common NarI core (underlined) is included in the sequences. This is not surprising since conformational and thermodynamic compatibilities of fluorine containing AF and AAF models have well been documented (20,30,35). A similar elution pattern was observed for the FAAF-modified 12-mer and FAAF-modified 16-mer NarI sequences; however, the order of elution of G$_1$ and G$_3$ was reversed (compare Figure 2a with Figure 2 in Ref. 20).
the loss of the unmodified guanine nucleotides is observed in the LC/MS spectra. This is shown in Supplementary Figure S4 for the 3′ digest of the -G1(FAAF)G2CG3-ODN. The ions observed at \( m/z \) 659.5 and \( m/z \) 989.7 are the (M-3 H)\(^+\) and (M-2 H)\(^+\) ions formed from the 5′-CT CTCCG1(FAAF)G3′-ODN digest fragment. The observation of these ions confirms that this ODN is modified on the G closest to the 5′ end. The LC/MS analysis of the 5′ digest of the second modified ODN to elute is shown in Supplementary Figure S5a and 5b. The exonuclease digestion of this particular reaction product was particularly slow and evidence for endonuclease activity is observed in the mass spectra. All the Y fragments observed in Supplementary Figure S5 are (M-3 H)\(^+\) ions. The Y10 and Y9 fragments at \( m/z \) 1069.2 (5′-G2CG3(FAAF)CCATCAC-3′) and \( m/z \) 959.5 (5′-CG3(FAAF)CCATCAC-3′) are formed by consecutive cleavages of unmodified guanines, confirming that this reaction product is modified on the guanine closest to the 3′ end. LC/MS analysis of the exonuclease digests derived from the third singly-modified ODN to elute indicates that the FAAF group is attached to the central G in the sequence, -G1G2(FAAF)CG3-. LC/MS analysis of the 5′ digest (Supplementary Figure S6) show ions at \( m/z \) 1154.7 and \( m/z \) 769.5 corresponding to the (M-2 H)\(^+\) and (M-3 H)\(^+\) ions derived from the 5′-CTCTCG1(FAAF)-3′ digest fragment. The mass spectra acquired from the 5′-digest (Supplementary Figure S7) show (M-2 H)\(^+\) and (M-3 H)\(^+\) ions at \( m/z \) 1604.3 and \( m/z \) 1069.2 whose masses are consistent with 5′-G2(FAAF)CG3CCATCAC-3′ fragment. No ions formed by the loss of two guanine deoxynucleotides were observed in any of the mass spectra. The observation of ODN fragments with two G’s in both 3′ and 5′ digests confirms that the last singly modified ODN to elute from the reaction mixture is modified on the middle G.

**Circular dichroism**

Figure 3a shows an overlay of the CD spectra for the three FAAF-modified NarI–G1, –G2 and –G3 duplexes relative to the unmodified control (red). Unmodified and FAAF-adducted duplexes both displayed a positive and negative ellipticity at around 270 and 250 nm, respectively, which is an S-curve characteristic of a B-form DNA double helix. The modified duplexes displayed significant blue shifts relative to the unmodified duplex, NarI–G3 (6 nm) >> NarI–G1 ~ G2 (3 nm), indicating adduct-induced DNA bending. A concomitant increase in the positive intensity around 270 nm was noted in the order of G3 ~ G1 > G2, which could be due to the interaction of the intercalated S-conformeric FAAF with neighboring bases. We noted a similar blue shift and hyperchromic effect for the highly (75%) S-conformeric FAAF-modified NarI–G3 duplex (Figure 3b and Table 1 in Ref. 20).

More importantly, FAAF-modified duplexes exhibited sequence-dependent induced CD in the 290–320 nm range (ICD\(_{290-320\text{ nm}}\)). This finding is reminiscent of ICD\(_{290-350\text{ nm}}\), which has been used as a sensitive marker for the FAF-induced S/B/W-conformational heterogeneity (positive for S- and W- and negative for B-conformer) (12, 15, 20, 29, 36). In the present case, however, the FAAF-modified NarI duplexes exhibited negative dips, with the NarI–G2 duplex showing a greater dip than G1 or G3 duplexes (Figure 3a). This result could be due to a higher ratio (57%) of B-conformer for the NarI–G2 duplex.

**UV melting experiments**

Supplementary Figure S8 shows the UV melting profiles of the three FAAF–NarI duplexes and an unmodified control duplex, all at 6.4 \( \mu \)M. All duplexes showed typical monophasic, sigmoidal, helix–coil transitions with a strong linear correlation \( (R^2 > 0.9) \) between \( T_m^{-1} \) and \( \ln c \). Thermal and thermodynamic parameters calculated from UV melting are summarized in Supplementary Table S1. As expected, modified duplexes were destabilized thermally and thermodynamically relative to the control duplex. The magnitude of thermal \( (\Delta T_m) \) and thermodynamic \( (\Delta \Delta G) \) destabilization was in the order of NarI–G3 > NarI–G1 ~ G2 (-8.7 to -8.8°C, 3.3 to 3.7 kcal/mol, respectively) > NarI–G1 (-4.6°C and 2.0 kcal/mol, respectively).

**Differential scanning calorimetry**

Figure 3b shows differential scanning calorimetry (DSC) plots of excess heat capacity \( C_p^{ex} \) versus temperature for the FAAF–NarI duplexes relative to the unmodified duplexes and Y9 fragments at \( m/z \) 1069.2 (5′-G2CG3(FAAF)CCATCAC-3′) and \( m/z \) 959.5 (5′-CG3(FAAF)CCATCAC-3′) are formed by consecutive cleavages of unmodified guanines, confirming that this reaction product is modified on the guanine closest to the 3′ end. LC/MS analysis of the exonuclease digests derived from the third singly-modified ODN to elute indicates that the FAAF group is attached to the central G in the sequence, -G1G2(FAAF)CG3-. LC/MS analysis of the 5′ digest (Supplementary Figure S6) show ions at \( m/z \) 1154.7 and \( m/z \) 769.5 corresponding to the (M-2 H)\(^+\) and (M-3 H)\(^+\) ions derived from the 5′-CTCTCG1(FAAF)-3′ digest fragment. The mass spectra acquired from the 5′-digest (Supplementary Figure S7) show (M-2 H)\(^+\) and (M-3 H)\(^+\) ions at \( m/z \) 1604.3 and \( m/z \) 1069.2 whose masses are consistent with 5′-G2(FAAF)CG3CCATCAC-3′ fragment. No ions formed by the loss of two guanine deoxynucleotides were observed in any of the mass spectra. The observation of ODN fragments with two G’s in both 3′ and 5′ digests confirms that the last singly modified ODN to elute from the reaction mixture is modified on the middle G.

**Circular dichroism**

Figure 3a shows an overlay of the CD spectra for the three FAAF-modified NarI–G1, –G2 and –G3 duplexes relative to the unmodified control (red). \(\Delta T_m = T_m\) (modified duplex) – \(T_m\) (control duplex).

\(\Delta T_m\) are ±0.4, ±3.0 and ±4.0, respectively.

\(T_m\) are ±0.4, ±3.0 and ±4.0, respectively.

\(\Delta \Delta G\) = 58.9 eu and \(\Delta \Delta S\) = 47.0 eu, yielding similar overall free energies (NarI–G1, \(\Delta \Delta G\) = 3.7 kcal/mol and NarI–G2, \(\Delta \Delta G\) = 4.1 kcal/mol).

S/B/W conformational heterogeneity

Figure 4a shows the \(^19\)F-NMR spectra of FAAF–NarI 16-mer G1–, G2– and G3-duplexes measured at 5°C, in which \(^19\)F signals are in slow chemical exchange. These NarI-FAAF duplexes exhibited three to five \(^19\)F signals, each representing a particular conformation. The percent population ratios shown were calculated on the basis of line simulations as shown in Supplementary Figure S9. Assignments of the different \(^19\)F signals of each duplex were necessary to carry out meaningful structure-activity-relationship studies. The signal assignments in Figure 4a were made initially on the basis of chemical exchange, ring current effect and chemical shift pattern recognition as have been done for a number of FAAF- and FAF-adducts in various sequence contexts (30,35). It has been demonstrated that AF and AAF adducts adopt the S/B- and S/B/W-conformational equilibrium, respectively (Figure 1c and d) and their \(^19\)F chemical shifts are independent of overall sequence and its length, but strongly rely on the nature of the bases flanking the lesion (15,30). The major \(^19\)F signals in Figure 4a correlate well with the S/B/W-profiles reported previously for FAAF adducts (15), i.e. B-, S- and W-conformers going from downfield to upfield, i.e. –115.0 to –115.5, –115.5 to –117.0 and –117.0 to –118.0 ppm, respectively. Additional signals were observed in the –114.0 to –115.0 ppm range for the NarI–G2 and –G3 duplexes (Figure 4a, see Supplementary Table S2 for exact chemical shifts). Consistent with this observation, their proton spectra displayed a mixture of broad imino signals arising not only from those involved in Watson–Crick hydrogen bonds (12–14 ppm), but also from the lesion site and its vicinity (11–12 ppm) (Supplementary Figure S10).

To complement the \(^19\)F signal assignments, we additionally conducted a set of comparative spectral analyses using control. Table 1 summarizes the thermal and thermodynamic parameters derived from these DSC curves. Consistent with the UV melting data, the NarI–G3 duplex was most destabilized (\(\Delta \Delta H = 24.7\) kcal/mol, \(\Delta \Delta G_{37°C} = 4.7\) kcal/mol, \(\Delta T_m = –8.3°C\)), followed by NarI–G2 (\(\Delta \Delta G_{37°C} = 4.1\) kcal/mol, \(\Delta T_m = –7.9°C\)). NarI–G1 was the least affected (\(\Delta \Delta G_{37°C} = 3.7\) kcal/mol, \(\Delta T_m = –5.3°C\)).

In contrast, NarI–G2 and –G3 duplexes possess higher populations of B-conformer (46 and 57%, respectively), thus exhibiting lower differences in the enthalpy values (\(\Delta \Delta H = 21.9\) kcal/mol and \(\Delta \Delta H = 18.6\) kcal/mol, respectively) (Table 2). The relatively small enthalpy differences observed for the G1 and G2 duplexes could be attributed to the presence of S- and W-conformers in addition to B-conformer. As expected, entropy compensation was less in these two duplexes (NarI–G1, \(\Delta \Delta S = 58.9\) eu and NarI–G2, \(\Delta \Delta S = 47.0\) eu), yielding similar overall free energies (NarI–G1, \(\Delta \Delta G = 3.7\) kcal/mol and NarI–G2, \(\Delta \Delta G = 4.1\) kcal/mol).
three FAAF-12-mer duplexes in the non-NarI sequences (Figure 4b) in otherwise identical flanking sequence contexts (CG*G, GG*C and CG*C context for G1, G2 and G3, respectively). The top trace in Figure 4b is the 19F-NMR spectrum of a FAAF-modified 12-mer duplex (5'-CTTCTG*CCTC-3') whose S/B/W conformational profiles have been well characterized (15). It should be noted that this non-NarI 12-mer duplex contains the identical CG*C flanking sequence context as the 16-mer NarI–G3–FAAF duplex. Comparison of the two spectra (i.e. top traces of Figure 4a and b) revealed a parallel trend both in terms of chemical shifts and population ratios (Table 2 and Supplementary Table S2), supporting the conformational assignments. This is consistent with our previous findings that the electronic environment for the 19F signals of AF and AAF adducts are strongly modulated by the nature of flanking bases (15, 30). Similarly, we prepared two additional FAAF-modified non-NarI 12-mer duplexes (5'-CTTCTG*GCTC-3' and 5'-CTTCTC GG*CCTC-3') with the same flanking base contexts (underlined) as the NarI–G1 and –G2 duplexes, respectively. Figure 4a and b compares the 19F-NMR spectra of all three NarI 16-mer and non-NarI 12-mer duplexes side by side. The 19F signal profiles, as indicated by dotted lines (pink, B; red, S; green, W) for G1 > G2 > G3 of each sequence context, match quite well overall despite of slight variations observed in chemical shifts and population ratios, particularly for the GG*C sequence context. Whereas the S- and W-conformer signals were prone to shift, the B-conformer signal appeared to be steady at -115.5 ppm. This trend is more apparent in Supplemental Figure S11, in which the two FAAF-modified sequence series (NarI-16-mer versus non-NarI-12-mer) are compared in a pair for each -CG*G-, -GG*C- and -CG*C- sequence contexts. It is plausible that the carcino- gen moiety in the major groove of the B-conformer is not subjected to the ring current effect, as the S- and W-conformers would be (14). We were unable to identify the minor signals (asterisked) in the 16-mer NarI–G2– (<19%) and –G3–FAAF duplexes, although their downfield shifts relative to the B-conformer imply B-like conformers, in which the fluorine containing carcinogen moiety is exposed.

Figure 4c shows the 19F-NMR spectra of FAF-modified 12-mer duplexes with the same NarI sequence contexts, which have been thoroughly characterized (20). The B/S conformer population ratios were determined to be 42%:58%, 69%:31%, 35%:65% for FAF-modified NarI–G1, –G2 and –G3, respectively, at 5°C (Table 2) (20). Although the chemical shift difference (0.4–1.0 ppm) for the B and S conformer of FAAF (Figure 4a) is significantly smaller than that (~1.5 ppm) of the FAF counterparts, their overall S/B ratios appear to match (Figure 4a and c). The B/S/W population ratios for the FAAF–NarI–G1, –G2 and –G3 16-mer duplexes were 46:34:20, 57:15:9 and 13:61:26, respectively (Table 2). In both the FAAF- (Figure 4a) and FAF- (Figure 4c) NarI duplexes, the population of S-conformer decreased in the order of G3 > G1 > G2 and that of the B-conformer decreased in the reverse order, G2 > G1 > G3. This comparative analysis was based on the assumption that structurally similar FAAF would experience similar sequence effects on their conformational profiles as observed by FAF in different sequence contexts of the NarI sequence (20). As expected, the aminofluorene-induced B/S-heterogeneity is strongly dependent on the nature of the flanking sequences, regardless of whether the lesion has the bulky acetyl group on the central
nitrogen linking the carcinogen and the modified guanine, thus validating our assumption.

**Dynamic $^{19}$F-NMR**

Figure 5 shows the $^{19}$F-NMR spectra of the three FAAF–NarI duplexes as a function of temperature (5–60°C). Whereas the three $^{19}$F signals in each duplex were in slow exchange at 5°C, the two downfield B- and S-signals became exchange broadened, giving rise to coalescent signals at around 30, 40 and 25°C for G1, G2 and G3, respectively. In all cases, the merged signals coalesced with the upfield W-signal at around 60°C. All three NarI duplexes showed relatively strong off-diagonal contour peaks of the major signals in the exchange spectra (data not shown), confirming their chemical exchanges.

**UvrABC incisions of FAAF-adducts on NarI sequence**

Figure 6 shows the kinetic assay results, in which 55-mer FAAF-modified DNA duplex substrates were incised by UvrABC nuclease. These substrates were radioactively labeled at the 5'-end of the adducted strand. The major incision products can be seen as 18-mer (NarI–G1), 19-mer (NarI–G2) or 21-mer (NarI–G3) separated on a urea–PAGE gel under denaturing conditions (Supplementary Figure S12). The incision occurred at the eighth phosphate bond 5' to the modified nucleotide, which is consistent with the previously reported results of UvrABC incision (11,32).

Quantitative analysis of the incision indicated that the substrates were incised at different efficiencies, depending on where the damage site was located in the sequence (Figure 6). Specifically, the N-acetylated FAAF adducts at NarI–G1 and NarI–G3 displayed similar rates of incision, whereas NarI–G2 had a much lower rate of incision, G3 (100%) > G1 (93%) > G2 (32%) (Figure 6c, Table 2). For comparison, we also determined the UvrABC incision of FAF adducts in the same NarI sequence context. As shown in Figure 6b and c, the N-deacetylated FAF adducts in the same NarI sequence context were repaired 2- to 3-fold less than FAAF. Despite having similar B/S-conformer profiles (Figure 4 and Table 2) the incision efficiency of FAF adducts at the three different sites in the NarI sequence followed the order of G1 (44%) ≈ G2 (43%) > G3 (25%), where the percentages were calculated relative to FAAF NarI–G3 (which was the most efficiently incised).

**DISCUSSION**

It is well known that DNA sequence is a major determining factor for repair outcomes of site-specifically modified bulky DNA lesions. In this study, we examined the conformational heterogeneity and thermodynamics of
FAAF and FAF at three different guanine positions (G₁, G₂ and G₃) of the well-known NarI recognition sequence. Moreover, we obtained NER data of these adducts using the E. coli UvrABC system. Table 2, which summarizes the S/B/W solution conformational heterogeneity, Tₘ and NER efficiency results, presents strong evidence that the NER repair efficiencies of AAF and AF adducts in the NarI sequences are modulated by their conformational and thermodynamic properties.

**FAAF-induced B/S/W-conformational heterogeneity**

Our combined ¹⁹F-NMR/ICD results show that FAAF adduct in a well-known mutational hotspot NarI sequence exist in a mixture of B/S/W conformers with varying populations (Figure 4a, Table 2). A greater population of syn-glycosidic S-(61%) and W-(26%) conformers was observed in NarI–G₃, in which the lesion is flanked with C on both 5’- and 3’-ends (-CG₃*C-). This result is consistent with the preferred syn-conformation adopted by duplexes modified by AF (20), 2-amino-3-methylimidazo(4,5-f)quinoline (IQ) (38-40) and 2-amino-1-methyl-6-phenylimidazo(4,5-b)pyridine (PHIP) (41), with the same -CG*C- contexts, in either NarI or non-NarI sequences (20,38,39,41). The mostly syn NarI–G₃ duplex appeared to be distorted, bent or possibly formed a B–Z junction, as evidenced by a significant blue shift and hyperchromic effect in CD (Figure 3a) (42). The latter was probably due to the n–n stacking interaction between the intercalated aminofluorene and flanking base pairs. On the other hand, the NarI–G₂ duplex (-G₁G₂*C-) exhibited largely the anti-B-conformer (57%) along with S- (15%), W- (9%) and two unidentified minor conformers (~19%). In comparison to NarI–G₃, the NarI–G₂ duplex exhibited smaller blue shift and hyperchromic effect (Figure 3a), suggesting lesser disturbance of the double helical DNA structure. These results indicate the heterogeneous nature of AAF in the NarI sequence and are consistent with a previous CD study that showed a major DNA distortion for AAF at G₃ adduct compared to G₁ and G₂ (42). Similarly, Veaute et al. (43) conducted a DNase I footprint study on the NarI sequence and showed that AAF at the G₂ position inhibits DNase I digestion of DNA at up to five bases in the modified strand and four bases in the complementary strand. In contrast, inhibition at the G₁ and G₃ positions was extended to eight and six bases, respectively in the modified strand.

The G₃ and G₂ duplexes are chemically isomeric, differing only in the direction of the G:C base pair at the 5’-position (e.g. C:G → G:C). Such a polarity swap is clearly responsible for the rather dramatic conformational shift from S- (61 to 15%) to B- (13 to 57%) and W-conformation (26 to 9%) (Table 2). A similar polarity switch at the 3’-end of the NarI–G₁ duplex resulted in varying degrees of conformational shift in S- (61 to 34%), B- (13 to 46%) and W-conformation (26 to 20%).
As expected, FAAF-modification at the three guanines of the 16-mer NarI sequence resulted in thermal ($\Delta T_m = -5.3$ to $-8.3^\circ C$) and thermodynamic ($\Delta \Delta G_{37^\circ C} = 3.7$--4.7 kcal/mol) destabilization relative to the unmodified control duplex (Table 1). The destabilizing effect of the FAAF modification was sequence-dependent and was related to the S/B/W-conformational profile. As summarized in Tables 1 and 2, the highly S-conformeric NarI–G$_3$ duplex (61%) promoted lesion stacking and disrupted the lesion site Watson–Crick base pairs, resulting in thermal ($\Delta T_m = -8.3^\circ C$) and enthalpic destabilization ($\Delta \Delta H = 24.7$ kcal/mol). In contrast, the highly B-conformeric (57%) NarI–G$_2$ duplex exerted less enthalpy change ($\Delta \Delta H = 18.6$ kcal/mol). As expected, NarI–G$_1$ (46% B, 34% S) produced an intermediate change in enthalpy ($\Delta \Delta H = 21.9$ kcal/mol). In all cases, however, enthalpy–entropy compensation resulted in a small overall difference ($\sim 1$ kcal/mol) in thermodynamic destabilization (Table 1). A similar case could occur if the W-conformer was considered as a thermodynamic destabilizer, G$_2$ (26%) > G$_1$ (20%) > G$_3$ (9%). We previously studied three fully paired FAAF-modified 12-mer duplexes in the same NarI sequence contexts (20). The UV melting results showed that FAAF modification destabilizes the duplexes ($\Delta T_m = -6.8$ to $-9.4^\circ C$, $\Delta \Delta G = 4.2$--4.6 kcal/mol) similarly. The highly S-conformeric (65%) NarI–G$_3$ duplex resulted in thermal destabilization ($\Delta T_m = -8.3^\circ C$), whereas the highly B-conformeric (69%) NarI–G$_2$ duplex exerted less destabilization ($\Delta T_m = -6.8^\circ C$) (Table 2) (20).

**Conformation-specific nucleotide excision repair**

The *E. coli* UvrABC system displayed significant differences in repair of the FAAF adduct at each guanine position (G$_1$, G$_2$, and G$_3$) of the NarI sequence. The NarI–G$_3$ duplex showed considerably lower efficiency than NarI–G$_1$ or NarI–G$_3$, [G$_1$ (100%) > G$_1$ (93%) > G$_2$ (32%)] (Figure 6). It is clear from Table 2 that these NER results are in good agreement with the order of the S-conformer population [G$_3$ (61%) > G$_1$ (34%) > G$_2$ (15%)], but are in exactly the reverse order of the population of B-conformer, [G$_2$ (57%) > G$_1$ (46%) > G$_3$ (13%)]. This data suggest that the S-conformation is recognized and incised by *E. coli* NER dominantly over the B-conformation. We reported previously a similar conformation-specific NER results on a series of FAAF-modified duplexes (16, 30).

The carcinogen in the highly S-conformer NarI–G$_3$ is base-displaced at the lesion site, thus resulting in a major disturbance in the DNA helical structure ($\Delta T_m = -8.3^\circ C$, $\Delta \Delta G_{37^\circ C} = 4.7$ kcal/mol) (Table 2). This finding is contrasted with the 57% B-conformer NarI–G$_2$ duplex, which maintains Watson–Crick base pairs at the lesion site ($\Delta T_m = -7.9^\circ C$, $\Delta \Delta G_{37^\circ C} = 4.1$ kcal/mol). Similar correlations could be made with either the W-conformer alone, G$_3$ (26%) > G$_1$ (20%) > G$_2$ (9%) or the syn-conformation (combined S and W), G$_3$ (87%) > G$_1$ (54%) > G$_2$ (24%).

For comparison, we also determined the UvrABC incisions of FAAF-adducts in the same NarI sequence context. The two lesions revealed a similar B/S conformer heterogeneity in the NarI sequence context (Figure 4). Therefore, the expectation was that FAAF would show a similar NER profile as FAAF, i.e. S/W-conformer promotes NER over B-conformer. However, the NER results revealed that incision efficiency was in the order of G$_1$ ≈ G$_3$ > G$_2$ (Figure 6, Table 2). At first, this result appears to be in line with the B-conformer population. It should be noted that FAAF is repaired consistently 2- to 3-fold less than FAAF (Figure 6c, Table 2). This result is a general trend reported in the literature, although much greater differences in incision efficiency between AF and AAF have been noted (11, 44). As a result, the difference between G$_1$ and G$_2$ of FAAF is not statistically significant ($P = 0.83$), but their difference with G$_3$ is significant ($P < 0.0001$).

The incision differences between FAAF and FAAF seem to suggest that, in addition to the sequence-dependent adduct conformation, the acetyl group in FAAF may play a role in DNA damage recognition by UvrABC. The only structural difference between FAAF and FAAF is the absence of a bulky acetyl group on the linking nitrogen of the former (Figure 1a). It has been documented that N-acetylated FAAF adducts in fully paired duplexes produce a mixture of complex S/B/W-conformers, whereas N-deacetylated FAAF adopts a simple exchangeable S/B-equilibrium (15, 30). Thus, it is clear that the N-acetyl group is responsible for generating up to 26% W-conformer in the NarI sequence (Figure 4). The bulkiness of the acetyl group with its possibility for cis and trans rotamer transitions about the amide bond (14, 15, 45) may facilitate the repositioning of the fluorenyl rings into the minor groove from the S conformation. This conformational rearrangement is relatively straightforward since it does not require a change in the glycosidic bond, which is syn in both cases. We observed a good correlation between the proportion of W-conformation and NER efficiency of FAAF.

Moreover, although FAAF and FAAF have similar S/ B-conformational profile (Figure 4), the N-acetyl group in the latter could act as a ‘conformational locker’ to raise the energy barriers among conformers. Such a scenario, i.e. higher energy barriers of FAAF vs. FAAF, is plausible and might contribute to a greater disturbance in DNA, and thus greater repair. By contrast, the N-deacetylated FAAF adopts a facile interchangeable S/ S-equilibrium (<2 kcal/mol) that triggers weaker binding affinities with the damage-recognition protein UvrA. A recent crystal study indicated that the UvrA dimer does not contact the lesion site directly, but rather binds DNA regions on both sides of the modification and primarily recognizes adduct-induced unwinding, bending and deformity in the overall DNA structure (25). Furthermore, DNA damage recognition in *E. coli* NER is achieved through a sequential 2-step mechanism (46). The initial step is to recognize the adduct-induced distorted DNA structure. After strand opening at the damage site, the DNA adduct structure is further recognized or verified in a second step, which may facilitate the flipping of the adducted nucleotide (47,48). Therefore, it is possible that, for FAAF, the second step of recognition plays a more
important role than the first step, whereas the first step is a
dominant recognition for FAAF.

The order of NER efficiencies described here is roughly
consistent with bacterial NER data on AAF adducts
embedded in a similar NarI sequence (17): G1 (100%),
G3 (66%) and G2 (18%). Sequence dependence was also
found in human NER of AAF adducted in the NarI
sequence (18). In contrast to the E. coli
found in human NER of AAF adducted in the
NarI sequence, the incidence was more repairable, followed by G3 (68%) and G1 (38%). Despite differences in the nature of proteins
involved in prokaryotic and eukaryotic NER, the two
systems show similar involvement of β-hairpin intrusion
as damage recognition factors (49). Liu et al. (50) found a
general qualitative trend toward similar relative NER
incision efficiencies for 65% of bulky benzo[a]pyrene
and equine estrogen substrates. Similar to bacterial
UvrA, Rad4 (XPC) in yeast also recognizes helical disto-
tion to sense DNA damage; unlike bacteria, yeast use a
base-flipping mechanism for repair (26). Therefore, the
efficiency of repair depends not only on the damage rec-
ognition step, but also on other factors, such as ease of
base flipping.

In summary, our structural and thermodynamic data
provide valuable conformational insights into the
sequence-dependent UvrABC incisions of the bulky
FAF and FAAF adducts in the NarI sequence context.
Repair of the bulky N-acetylated FAAF adduct seems to
occur in a conformation-specific manner, i.e. the highly S/
W-conformeric G3 and G1 duplexes incised considerably
more efficiently than the G2 duplex (G1 ~ G1 > G2) (Table
2). These results were supported by melting and thermo-
dynamic data. Not surprisingly, FAF was repaired 2- to
3-fold less than FAAF; however, the order of incision
efficiencies was the reverse of that in the FAAF case.
We considered the so-called N-acetyl factor and lesion-specific recognition mechanism for the different
orders of incision for FAF and FAAF. Finally, the tem-
perature dependence of the S/W-conformational equilibria of the FAAF-adducts in the NarI sequence
could provide valuable opportunities for
conformation-specific NER utilizing thermophilic
UvrABC proteins (51). Taken together, the results of
this study demonstrate the complexity of NER mechan-
isms of bulky DNA lesions.
